

Aliasing in Fractional Designs

Background

Factorial designs, for example 2^k and 3^k , are discussed elsewhere in this series (*see* **Factorial Experiments**). Fractional factorial designs such as the 2^{k-p} and 3^{k-p} designs are discussed in **Fractional Factorial Designs**, while **Plackett–Burman Designs** discusses Plackett–Burman designs. In this chapter, we discuss the aliasing (confounding or confusion) among effect estimates that occurs with the regular two-level fractional factorial (2^{k-p}) designs, nonregular two-level designs, and the regular three-level fractional factorial (3^{k-p}) designs.

If k factors, each with two levels, are studied by obtaining a single observation at each of the $n = 2^k$ factor-level combinations (design points), then the design is called an *unreplicated 2^k factorial design*. (The two levels of each factor are commonly labeled +1 and –1 with the assignment being arbitrary.) An example of one of the smallest full factorial designs is the 2^3 , that is, $k = 3$ with the factor levels labeled –1 and +1. Table 1 shows the effect (**X**) matrix. The A , B , and C columns represent the design matrix. In other words, the first observation is obtained by setting factors A , B , and C at their –1 or “low” level and observing the response. The other observations are obtained similarly. In practice, the order of experimentation should be randomized in an attempt to balance out any noise, such as a time effect.

In this example there are eight observations so eight quantities can be estimated. The effect matrix

is simply the **X** matrix in a regression setting. The I column represents the intercept or overall mean. The AB , AC , BC , and ABC columns are used to calculate the two- and three-factor interactions which we abbreviate as $2fi$ and $3fi$. (These columns are created by multiplying the columns associated with the component factors element by element.) Note that if all quantities are to be estimated, the model is saturated, and without replication, there is no error term available for **hypothesis testing**.

Aliasing in 2^{k-p} Experiments

In this section we introduce the concept of aliasing in the simplest case, the half fraction or 2^{k-1} , followed by aliasing in the general 2^{k-p} .

Aliasing in 2^{k-1} Experiments

Suppose, instead of the full factorial, a half fraction or 2^{3-1} is used by only running the four rows where $ABC = I$. These rows are marked with an * in Table 1. (Note that a 2^{3-1} design is not commonly used in practice. We include it here for strictly pedagogical reasons.) Inspection of these rows reveals the following equalities: $I = ABC$, $A = BC$, $B = AC$, $C = AB$. Here, $I = ABC$ is denoted the *defining relation* and the pairs are known as *aliases*. We can actually determine the alias pairs by multiplying the defining relation by each effect. When doing so, we note that each column consists of half –1s and half +1s, so if a column is multiplied by itself we get a column full of 1s, or I .

For example, $A^2 = A \cdot A = I$ and $(ABC)^2 = A^2B^2C^2 = I \cdot I \cdot I = I$. Multiplying the defining relation by A gives $A \cdot I = A \cdot ABC$, which simplifies to $A = BC$. The alias pairs $B = AC$ and $C = BD$ are derived similarly. We use this method of determining the alias structure as opposed to writing out the effect matrix and inspecting for equalities. Note that the effect of ABC cannot be separated from the overall mean. This pair of effects, as well as the pairs A and BC , B and AC , and C and AB , are completely *confounded* or confused. In other words, when the experiment is run and the data are analyzed, we will only have four estimates.

Suppose, for example, that the estimate of the alias pair $A = BC$ of effects is quite large and is therefore of interest. Without additional data, we cannot

Table 1 2^3 Full factorial. Rows with * form the 2^{3-1} fraction with $I = ABC$

Row	I	A	B	C	$\cdot$	AB	AC	BC	ABC
1	1	–1	–1	–1	$\cdot$	1	1	1	–1
2*	1	1	–1	–1	$\cdot$	–1	–1	1	1
3*	1	–1	1	–1	$\cdot$	–1	1	–1	1
4	1	1	1	–1	$\cdot$	1	–1	–1	–1
5*	1	–1	–1	1	$\cdot$	1	–1	–1	1
6	1	1	–1	1	$\cdot$	–1	1	–1	–1
7	1	–1	1	1	$\cdot$	–1	–1	1	–1
8*	1	1	1	1	$\cdot$	1	1	1	1

2 Aliasing in Fractional Designs

determine if the effect is due to A , or BC , or both! The only way to structurally remove the confounding is to collect more data. However, if we assume that two-factor and higher-order interactions are negligible, then there is essentially no confounding and we may assume we are estimating the overall mean, A , B , and C . The actual effect matrix used would be just the columns to the left of the dots in Table 1. Note that the column labeled C is also the AB column. This leads to another method of creating this same design, that is, write out the 4×4 effect matrix for a 2^2 factorial in factors A and B and assign factor C to the AB column. Thus we may also refer to $C = AB$ as the *design generator*.

The assumption that $2fis$ are less likely to be important than main effects, and that $3fis$ are less likely to be important than $2fis$ (and so on) is known as the *hierarchical ordering principle*. While many experimenters apply this principle by assuming $3fis$ and higher interactions are negligible, it is indeed a strong assumption that $2fis$ are negligible.

Aliasing in More Highly Fractionated 2^{k-p} Experiments

Generally, screening designs involve more factors and tend to be a bit larger than the example in the previous discussion. For example, if seven factors are studied in $n = 16$ runs, the design is an unreplicated 2^{7-3} or a $1/2^3 = 1/8$ fraction of the 2^7 factorial. Recall that one design generator is required for a 2^{k-1} design. In general, a 2^{k-p} design requires p design generators. Chen and Lin [1] provide a succinct description of design generators and defining relations, which we discuss next.

For any 2^{k-p} design, let the factors be represented by the letters A , B , and so on. Then any product of letters is called a word and we can choose a (nonunique) set of p words, which generate the design. The p selected *generators* determine the design. Let I be the identity defined so that, for all words W , $IW = WI = W$ and $W^2 = I$. This enables us to write the product UW of two words U and W in a minimally reduced form. The set of distinct words formed by all possible products involving the p generators gives the defining relation, which contains 2^p terms, including the identity term I . The words in the defining relation correspond to those products of the design columns that are the same as the identity

I . A design is uniquely determined by the defining relation and vice versa.

Suppose the experimenter wishes to study seven factors labeled A , B , C , D , E , F , and G . One approach for creating this design is to write out the 16×16 effect matrix for a 2^4 factorial in factors A , B , C , and D (the so-called basic factors). The factors E , F , and G are then assigned to columns representing interactions between the first four factors (the design generators). This assignment should not be made arbitrarily as different designs will have different properties. This is elaborated upon subsequently. Table 2 shows such a design where $E = ABC$, $F = BCD$, and $G = ACD$ are the design generators. For the design in Table 3, we have $E^2 = ABCE$, $F^2 = BCDF$, and $G^2 = ACDG$. Combining these we have $I = ABCE = BCDF = ACDG$. Note however, that pairwise and three-way products of these terms are also equal to I , for example $(ABCE)(BCDF) = AB^2C^2DEF = ADEF$. Multiplying each of the other two pairs and the triple gives the defining relation

$$\begin{aligned} I &= ABCE = BCDF = ACDG = ADEF \\ &= BDEG = ABFG = CEF G \end{aligned}$$

Note that the defining relation has $2^3 = 8$ terms, including I , reflecting that it is a one-eighth fraction. Indeed if a 2^{7-4} design were used, the defining relation would have 16 terms.

As we did with the half fraction, we can find the full alias structure by multiplying the defining relation by individual effects. For example, multiplying by A gives $A = BCE = ABCDF = CDG = DEF = ABDEG = BFG = ACEFG$. This implies that when we estimate the effect of A , we are really estimating the combined effects of all terms in this string. If the three-factor and higher-order interactions are null (or negligible), then we can ignore such terms and assume the estimated effect is due to A . An abbreviated form of the alias structure is given in Table 3. Here we use another convention to represent the alias string where plus signs are used to show additivity among the effects in a string.

Suppose instead of design 1 in Table 2, we assigned E , F , and G as follows: $E = ACD$, $F = BCD$, and $G = ABCD$. Then the defining relation and alias pattern (abbreviated) are given in Table 4 for design 2.

Resolution and Aberration

Not all designs of the same resolution have the same *WLP*. When comparing two designs of the same resolution, say A and B , design A has less aberration than B if its first nonzero c_i is less than that of B . A also has less aberration than B if it is of higher resolution than B . For our two designs, then, D_1 has less aberration than D_2 . A design with *minimum aberration* within a class of designs is such that no other design exists with less aberration. (See Fries and Hunter [3] or **Minimum Aberration** for more information about aberration.)

All 2^{k-p} fractional factorials have a structure in which effects are either totally aliased (confounded) or not aliased at all and can be represented by a defining relation. In other designs, we may have effects that are partially aliased. Two effects are totally aliased if the **correlation** of their columns in the $\mathbf{X}$ matrix is -1 or $+1$, while if two columns have nonzero, but not perfect correlation, then their effects are partially aliased. Designs that have partially aliased effects are called *nonregular designs*. A popular series of nonregular designs was developed by Plackett and Burman [4] (see **Plackett–Burman Designs**). These designs have run sizes that are multiples of 4 and are a special class of Hadamard Matrices. Table 5 shows the 12-run Plackett and Burman design.

Table 5 Plackett–Burman 12-run design[illegible]

matrix $\mathbf{A} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{X}_1 = [(a_{ij})]$. Here, element a_{ij} measures the degree of aliasing between **main effect** i and interaction j . For example, if the first four columns of Table 5 are used to study four factors, the matrix $\mathbf{A}$ is as given in Table 6, ignoring higher-order interactions. From this we see that each main effect is partially confounded with three *2fis*, those that do not involve the main effect itself: $A = -1/3BC = -1/3BD = 1/3CD$, $B = -1/3AC = -1/3AD = -1/3CD$, $C = -1/3AB = 1/3AD = -1/3BD$, and $D = -1/3AB = 1/3AC = -1/3BC$. If 11 factors are studied in this 12-run design, then the main effect of each factor is partially confounded with 45 *2fis*, those not involving the factor. Plackett and Burman designs have this general property and are therefore resolution III designs. A complete alias table is given in Lin and Draper [5]. They also provide alias tables for Plackett and Burman designs of higher orders.

Aliasing in 3^{k-p} Designs

For three-level designs, we change our notation to 0, 1, 2 to denote the three levels of a factor. Because each factor has three levels, each main effect has 2 **degrees of freedom** and each *2fi* has 4 degrees of freedom. Since each column in the effect matrix has $df = 2$, we need two columns to designate a *2fi*. For example, the columns AB and AB^2 together represent the interaction effect

between factors A and B . The column AB is calculated as $A + B$ and AB^2 as $A + 2B$. Both calculations are done modulo 3 meaning the solution is the remainder left after dividing the quantity by 3. For example, $3(\text{mod}3) = 0$, $4(\text{mod}3) = 1$, and so on. It can be shown that A^2B results in the same sum-of-squares calculation as AB^2 so only one is needed. We use the convention that the first letter in an interaction is always first order and if it is not, we square the entire term to achieve this. Specifically, $A^2B(\text{mod}3) = (A^2B)^2(\text{mod}3) = A^4B^2(\text{mod}3) = AB^2(\text{mod}3)$.

So the effect matrix for the 3^3 design will have three columns for the three main effects, six columns for the three *2fis*, and four columns for the *3fi*: A , B , C , AB , AB^2 , AC , AC^2 , BC , BC^2 , ABC , ABC^2 , AB^2C , and AB^2C^2 . We can create a 3^{4-1} design by assigning the fourth factor D to one of the interaction columns, as we did when creating a 2^{k-1} design. If we let $D = ABC^2$ for example, then we have the defining relation $I = ABC^2D$. We determine the aliases of an effect by multiplying by both I and I^2 , or ABC^2D and $A^2B^2CD^2$. For our example, this leads to the alias structure shown in Table 7. More highly fractionated designs can be created by adding terms to the defining relation. See Montgomery [6] for more information on aliasing in 3^{k-p} designs.

Summary

In regular designs such as the 2^{k-p} and 3^{k-p} series, the defining relation can be used to determine what effects are confounded with each other, that is, effects that are aliases. Multiplying an effect by each term in the relation results in the effects that are confounded. In nonregular designs, the regression matrix $\mathbf{X}$ may be created by listing all effects. Then the alias matrix $\mathbf{A} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{X}_1$ shows the alias pattern, including effects that are partially confounded. This method may also be used for regular designs.

Table 6 Alias matrix of four factors in the Plackett–Burman 12-run design

	AB	AC	AD	BC	BD	CD
A	0	0	0	−0.33	−0.33	0.33
B	0	−0.33	−0.33	0	0	−0.33

Analysis of Variance

Introduction

It is hard to imagine a more commonly used data analysis technique than the analysis of variance, or simply, **ANOVA**. First introduced by Fisher [1, 2], (with Mackenzie [3]) for the analysis of agriculture experiments, which could be arranged as Latin squares (see **Latin Squares and Related Experimental Designs**) or randomized block designs (see **Blocking**), ANOVA has become ubiquitous in statistical practice. It is the standard approach for the analysis of most industrial experiments (e.g., see Box *et al.* [4], Montgomery [5], or Wu and Hamada [6]).

The aim of ANOVA, in short, is to determine if there exists a relationship between a dependent variable (or response variable) and one or more experimental factors. A relationship is identified by observing significantly different mean responses at the various settings of the experiment factors (factor levels). The ANOVA approach partitions the variability, and associated **degrees of freedom**, of the response into variability due to error and factor effects. Variability that is not explained by chance variation is taken as evidence of a significant effect.

Methodology

In many investigations, experimenters are interested in exploring the impact of two or more factors on the mean response of a process. The analysis of variance is a natural way to address this goal. Many studies have more than one factor, but for ease of presentation the single-factor (one-way) ANOVA is first presented, followed by generalizations to multifactor studies.

Suppose an experiment has been conducted with a single factor (e.g., temperature or pressure) at I levels. Further, suppose that there are n_i observations taken at each level ($i = 1, 2, \dots, I$), and thus, the experiment has $N = \sum_{i=1}^I n_i$ total observations. Let y_{ij} denote the j th observation ($j = 1, 2, \dots, n_i$) taken at level i . The one-way ANOVA model can be written as

$$y_{ti} = \mu_i + \epsilon_{ij} \quad \text{for } i = 1, 2, \dots, I \quad \text{and} \\ j = 1, 2, \dots, n_i \quad (1)$$

where μ_i is the mean response for the i th treatment, and the errors, ϵ_{ij} , are independent and identically distributed (i.i.d.) $N(0, \sigma^2)$ for all i and j . An equivalent alternative form for the ANOVA model is

$$y_{ti} = \mu + \alpha_i + \epsilon_{ij} \quad \text{for } i = 1, 2, \dots, I \quad \text{and} \\ j = 1, 2, \dots, n_i \quad (2)$$

where μ is the grand system mean over the I levels of the factor and α_i is the effect of the factor at level i . For the most part, this presentation focuses on model (2) because it is easily understandable in most industrial settings. That is, by setting the factor at level i , the system mean is changed by α_i beyond the grand mean μ .

The above model (2), as written, is not identifiable. If, for instance, one rewrites equation (2) as a regression model (e.g., Kutner *et al.* [7]), then the model matrix is not invertible. To address this issue, additional constraints are placed on the model parameters. The most common such constraint is to restrict the factor effects (e.g., the α_i 's) so that they sum to zero (more on this later). Although there are other constraints that can be used to make the model parameters estimable, this formulation lends itself to simple interpretation.

An important question that ANOVA addresses is whether there is evidence of differences among the mean response at the different factor levels. The factor effects, in conjunction with the constraint $\sum_i \alpha_i = 0$, can be interpreted as the impact on the response of setting the factor to level i above the process mean of the I levels, μ . So, if the mean response is the same at each level of the factor, then $\alpha_i = 0$ for all i . Consequently, an important objective of ANOVA is to test the null hypothesis that all the factor effects (i.e., the α_i 's) are equal to zero *versus* the alternate hypothesis that they are not.

The operational idea behind one-way ANOVA is to use two estimators of σ^2 , one which is robust to the hypotheses and one which is not, to assess the evidence against the null hypothesis. Begin by constructing the total **sum of squares**,

$$SS_T = \sum_{i=1}^I \sum_{j=1}^{n_i} (y_{ij} - \bar{y})^2 \quad (3)$$

where $\bar{y}$ is the sample mean of all of the observations. The total sum of squares measures the total variability

2 Analysis of Variance

in the data. It can be written as,

$$SS_T = \sum_{i=1}^I \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2 + \sum_{i=1}^I n_i (\bar{y}_i - \bar{y})^2 \quad (4)$$

where $\bar{y}_i$ is the sample mean of observations at level i . This decomposition is a key feature of ANOVA.

The first term in the above decomposition, called the *error* (or *residual*) *sum of squares* and denoted SS_E , measures the squared deviations of observations from their respective treatment mean. Since the error variance is assumed to be constant across levels of the factor, the SS_E should not be impacted by departures from the null hypothesis and when properly normalized can be used to estimate σ^2 . The second term (the between treatment sum of squares, denoted SS_B) in the decomposition of the total sum of squares measures the squared deviations of the treatment means from the grand mean. Under the null hypothesis, this sum, properly normalized, can also be used to estimate σ^2 . On the other hand, when the null hypothesis is false this sum will be inflated.

Under the above model, the variance of the response at each level of the factor is σ^2 . Therefore, σ^2 can be estimated by pooling the sample variances from each level. Specifically, the pooled estimate of the population variance is

$$MS_E = \frac{\sum_{i=1}^I \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2}{N - I} \quad (5)$$

This estimator of σ^2 is called the *error mean square*, and is just the error sum of squares divided by its degrees of freedom. Similarly, σ^2 can be estimated using the between treatments sum of squares. Specifically, the between treatments mean square is

$$MS_B = \frac{\sum_{i=1}^I n_i (\bar{y}_i - \bar{y})^2}{I - 1} \quad (6)$$

This is simply the between treatment sum of squares divided by its degrees of freedom.

The above information is summarized in Table 1. The idea behind ANOVA is to use the two estimators of σ^2 to test the null hypothesis of the equality of treatments. This is done *via* their ratio $F = MS_B/MS_E$. Under the null hypothesis, both the mean squares are unbiased estimators of σ^2 , and the ratio has an F distribution with $(I - 1, N - I)$ degrees of freedom. When the null hypothesis is false, only the MS_E is an unbiased estimator, and MS_B will get large. Thus large values of the F statistic provide evidence against the null hypothesis. The p value for assessing the evidence against the null of the equality of treatment effects is found from the F distribution with $(I - 1, N - I)$ degrees of freedom.

Parameter Estimation and Contrasts

The parameters of the ANOVA model (2) are unknown and have to be estimated from the data. The lack of identifiability of the model in equation (2) is addressed by placing restrictions on the model parameters (i.e., $\sum_i \alpha_i = 0$). Specifically, one can rewrite equation (2) as a linear model with $\alpha_I = -\alpha_1 - \alpha_2 \cdots - \alpha_{I-1}$, without loss of generality. Next, the process mean, μ , and the α_i 's are estimated by **least squares**. When each group has the same number of observations (the data are balanced), $\hat{\mu} = \bar{y}$ and $\hat{\alpha}_i = \bar{y}_i - \bar{y}$. Here, the least squares estimators reinforce the intuitive interpretation of the factor effects. That is, the estimate of the factor effect is simply the difference between the treatment sample mean and the overall mean. So, the treatment effects measure the impact on the process mean of setting the factor to its i th level, after adjusting for the grand mean.

When the null hypothesis is true, one expects that the treatment sample means will be close to the grand mean of the data. Of course, there are

Table 1 One-way ANOVA table

Source of variation	Sum of squares	Degrees of freedom	Mean square	F statistic
Between treatments	SS_B	$I - 1$	$MS_B = \frac{SS_B}{I - 1}$	$F = \frac{MS_B}{MS_E}$
Error	SS_E	$N - I$	$MS_E = \frac{SS_E}{N - I}$	
Total	SS_T	$N - 1$		

other restrictions one could have chosen (e.g., see Searle [8, Chapter 5]) that would, in turn, give different meaning to the model parameters. It is important to note that software packages will report the same ANOVA table, but can use different default model restrictions. Therefore, in practice, one should be careful to ascertain the meaning of the model parameter estimates.

When the null hypothesis is rejected and one concludes that there is evidence that the treatment effects (or, equivalently, the treatment means) are different, the next obvious step is to investigate how these differences occurred. One way to approach this is to perform hypothesis tests for the equality for each of the pairwise differences of the treatment means, or factor effects (see Kutner *et al.* [7] for a discussion of multiple comparisons tests). More generally, a contrast is a linear combination of the treatment means in model (1), $L = \sum_i c_i \mu_i$ where $\sum_i c_i = 0$. The contrast is a comparison of two or more of the treatment means, and the pairwise differences used in the multiple comparisons test as a special case. It turns out that the contrast can be estimated by $\hat{L} = \sum_i c_i \bar{y}$. Hypotheses about the contrast can be evaluated and **confidence intervals** can be constructed using a t -distribution (see Kutner *et al.* [7, Chapter 17]).

ANOVA with Two Factors

The one-way ANOVA model is used to investigate the impact of one factor with two or more levels. Of course, many studies have more than one factor. We first consider the case when the sample sizes at each setting of the factors are identical (i.e., the data are balanced), in which case the analysis is a simple generalization of the one-factor model. When there are different numbers of observations at each setting, the data are said to be unbalanced.

To understand the multifactor ANOVA model, it is easiest to present the two-factor model and then mention how to generalize to any number of factors. In the same spirit as one-way ANOVA, multifactor ANOVA attempts to partition the total system variability, and degrees of freedom, of the data into variability due to error (within treatments) and variability due to the effects of factors (between treatments).

The two-factor ANOVA model, with factors labeled A and B , can be written as

$$y_{ijk} = \mu + \alpha_i + \beta_j + \eta_{ij} + \epsilon_{ijk}; \quad \text{for } i = 1, 2, \dots, I, \\ j = 1, 2, \dots, J, \text{ and } k = 1, 2, \dots, n_{ij} \quad (7)$$

where α_i is the effect of factor A at level i , and β_j is the effect of factor B at level j , η_{ij} is the interaction effect at levels i and j of factors A and B (see **Interactions** for details on interactions). As before, the errors, ϵ_{ijk} , are i.i.d. $N(0, \sigma^2)$ random variables for all i, j , and k . Let $N = \sum_{i=1}^I \sum_{j=1}^J n_{ij}$ be the total number of observations.

The two-factor ANOVA model, similar to the one-factor model, is not identifiable. Again, constraints on the parameters are required to make the model identifiable. Specifically, it is common to impose the restrictions $\sum_i \alpha_i = 0$, $\sum_j \beta_j = 0$, $\sum_i \eta_{ij} = 0$ and $\sum_j \eta_{ij} = 0$. For this model and these restrictions, the factor effects can be thought of as the impact on the system mean response when changing the levels of one of the factors. The interaction effect, η_{ij} is the joint impact on the system mean when factor A is at level i and factor B is at level j , beyond the individual effects of each factor.

Let $\bar{y}$ be the sample mean of all the observations, $\bar{y}_{i..}$ be the mean response at level i of factor A , $\bar{y}_{.j.}$ be the mean response at level j of factor B , and $\bar{y}_{ij.}$ be the mean response at levels i and j of factors A and B . For balanced data, the total sum of squares is the same as defined above, but the variability is partitioned to represent the model components; that is,

$$SS_T = SS_A + SS_B + SS_{AB} + SS_E \quad (8)$$

where the sums of squares for A , B and the interaction effect are, respectively,

$$SS_A = \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^{n_{ij}} (\bar{y}_{i..} - \bar{y})^2 \quad (9)$$

$$SS_B = \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^{n_{ij}} (\bar{y}_{.j.} - \bar{y})^2 \quad (10)$$

$$SS_{AB} = \sum_{i=1}^I \sum_{j=1}^J \sum_{k=1}^{n_{ij}} (\bar{y}_{ij.} - \bar{y}_{i..} - \bar{y}_{.j.} + \bar{y})^2 \quad (11)$$

Note that we are now using SS_B to denote the sum of squares for factors B .

4 Analysis of Variance

Table 2 Two-way ANOVA table

Source of variation	Sum of squares	Degrees of freedom	Mean square	F statistic
Factor A	SS_A	$I - 1$	$MS_A = \frac{SS_A}{I - 1}$	$F = \frac{MS_A}{MS_E}$
Factor B	SS_B	$J - 1$	$MS_B = \frac{SS_B}{J - 1}$	$F = \frac{MS_B}{MS_E}$
AB interaction	SS_{AB}	$(I - 1)(J - 1)$	$MS_{AB} = \frac{SS_{AB}}{(I - 1)(J - 1)}$	$F = \frac{MS_{AB}}{MS_E}$
Error	SS_E	$IJ(N - 1)$	$MS_E = \frac{SS_E}{IJ(N - 1)}$	
Total	SS_T	$N - 1$		

As before, the significance of each effect is assessed using the appropriate F statistic, with degrees of freedom associated with the numerator and denominator components, respectively. The corresponding ANOVA table for this model is shown in Table 2.

Note, the above sums of squares decomposition is appropriate when the treatment sample sizes are all the same. When they are not all equal, the decomposition breaks down. That is, when the n_{ij} are not all the same, the total sum of squares is not equal to the sum of SS_A , SS_B , SS_{AB} , and SS_E . This, in turn, impacts the distribution of the parameter estimates, the hypotheses being tested and the corresponding test statistics. Considerable attention has been drawn to AVOVA with unbalanced data, and several analysis strategies proposed (e.g., see Searle [9] and Milliken and Johnson [10]). Hypothesis tests in the unbalanced setting are often conducted by comparing the total sum of squares for a “full” model (the model with all effects present) to the total sum of squares for the “reduced” model (a model without the effect of interest). This is frequently called the *Type III analysis* (e.g., Milliken and Johnson [10, p. 150]). In this case, one is investigating the marginal explanatory power of an effect after including all other effects in the model. When all of the n_{ij} are equal, the Type III analysis hypothesis tests coincide with those for balanced datasets.

Generalizations

To generalize the ANOVA model to more than two factors, one simply augments the two-factor model with the appropriate number of main effects and

interactions. Indeed, one can also add all interactions of any order, if the degrees of freedom permit. When the degrees of freedom are not sufficient to estimate all interactions and experimental error, the higher-order interactions are usually not included in the model, under the assumption that they are negligible.

Checking Assumptions

Application of ANOVA is not simply the construction of a table and the computation of F statistics. Indeed a key step is the verification of the underlying model assumptions and this is a routine part of any ANOVA endeavor.

The ANOVA model assumes that the data are random samples from normal populations with the same variance and potentially different means. So the ϵ 's should be a random sample from an $N(0, \sigma^2)$ distribution. Though the exact errors are unavailable, these errors can be estimated by the **residuals** (the observed minus the expected response) (see **Residuals**). The validity of the model assumptions are usually assessed using several simple plots, some of which are now discussed.

The normality assumption is usually validated using a normal probability plot. This is done by plotting the ordered residuals *versus* the **percentiles** of the standard **normal distribution**. If the plot reveals a straight-line pattern, this is taken as evidence that the residuals are normally distributed, otherwise one concludes that the normality assumption is violated.

To verify that the residuals appear to be i.i.d., several separate plots are constructed. The plots attempt to see if there are any systematic departures from the i.i.d. assumption. Common plots to visualize

Table 3 Example data for the plutonium experiment

A	B	Replicate 1	Replicate 2	Replicate 3
Low	Low	4.08	4.54	4.07
Medium	Low	4.48	5.23	4.19
High	Low	5.66	5.04	5.59
Low	Medium	4.05	4.65	4.16
Medium	Medium	5.15	4.07	4.51
High	Medium	4.86	4.14	4.98
Low	High	4.64	4.95	4.36
Medium	High	4.11	4.66	4.14
High	High	5.36	5.11	4.93

such violations are time plots (plot the residuals against the order in which they were collected), plotting the residuals *versus* their treatment and also plotting the residuals *versus* the expected response. In each case, any systematic pattern that is visualized (short of random scatter) is taken as evidence that the i.i.d. assumption has been violated.

If the residual plots reveal departures from the model assumptions, then it is common to take remedial measures. These measures usually take the form of transforming the responses, the predictors, or both. For instance, when the distribution of the residuals appears to exhibit **skewness** or nonconstant variance, a Box–Cox transformation (*see* **Box and Cox Transformation**) of the response variable is often used to make the distribution of the residuals appear approximately normal. In more complicated settings, one may elect to model both the mean and the variance (*see* **Generalized Linear Models**).

Example

Researchers at the Los Alamos National Laboratory were interested in studying a treatment process that creates a type of plutonium alloy with a high decay rate that can eventually be used for accelerated testing (for details on the physics, see Freibert *et al.* [11]). The experiment is modified for this illustration. Consider a designed experiment to determine which of two factors, at three levels (low, medium, and high) impact the decay energy (in MeV) and should be subsequently studied to optimize the process. The factors *A* and *B* relate to different chemical compositions and processing temperatures, respectively. The data for three replicates of the nine possible levels settings are shown in Table 3.

The ANOVA table for these data is shown in Table 4. Notice that the *p*-value for the *F*-statistic for factor *A* is quite small (*p* value = 0.0027) whereas the *p* values for the remaining two effects are relatively large. Consequently, only factor *A* has a significant effect on the mean response, which increased on average from 4.39 MeV when *A* was at its low level to 5.07 MeV at the high level of factor *A*. There is no clear evidence that factor *B* affects the mean response or that there is any interaction between the two factors. One should not conclude from the analysis that the processing temperature (factor *B*) is not important. Instead, the data indicated that there was not a significant difference in the process mean over the range of temperatures explored.

In the interests of space, the residual analysis and multiple comparisons tests are not presented. However, a complete investigation of the data will always include these steps. Such analysis must be routine practice.

Comments

There are some final things that should be mentioned. Firstly, this brief presentation has considered only data that arise from completely randomized designs. Randomized block (*see* **Blocking**), **Latin square** (*see* **Latin Squares and Related Experimental Designs**), and split-plot (*see* **Split-Plot Designs**) designs are all examples of designs with **randomization** restrictions (e.g., see Montgomery [5]). When conducting an ANOVA in these settings, it is important to integrate the additional random effects into the analysis.

One must also be cognizant that the data are assumed to be continuous. Frequently, the responses are counts or discrete values. Direct application of

6 Analysis of Variance

Table 4 ANOVA table for the plutonium experiment

Source of variation	Sum of squares	Degrees of freedom	Mean square	<i>F</i> -statistic	<i>P</i> value
Factor <i>A</i>	2.42	2	1.21	8.34	0.0027
Factor <i>B</i>	0.32	2	0.16	1.09	0.3565
<i>AB</i> interaction	1.09	4	0.27	1.87	0.1601
Error	2.62	18	0.15		
Total	6.45	26			

ANOVA in these settings is inefficient. One possible solution is to transform the data (e.g., square root or log). Such transformations can also be a good strategy for dealing with continuous data that do not follow a normal distribution. An alternate solution for discrete data is to use a **generalized linear model** [12] instead of the ANOVA model.

Blocking

Introduction and Definition

When planning an experiment, experimental units can be grouped into *blocks* in such a way that units in the same block are expected to give similar responses. This allows more precise comparisons of treatments to be made because, when performing a data analysis, the variation between blocks can be separated from the variation within blocks.

The *experimental units* are the objects to which the *treatments* (typically combinations of levels of several input factors) are applied, so that each unit receives only one treatment, while different units can receive different treatments. They are typically *runs* of the process which is the subject of experimentation, or people (*subjects*) who are under study. In an experiment on the mixing of pastry dough that we use throughout as an illustration, the treatments were the eight combinations of low and high levels of the flow rate of materials into the mixer, the initial moisture content in the mix, and the screw speed at which the mixer was turned. The experimental units were eight runs of a food extrusion cooker used to mix the dough. In other contexts, the experimental units could be different products, animals, pieces of land, and so on. Irrespective of the treatments applied, the units will give different responses. If there are no known patterns of variation among the units, the treatments should be applied to the units completely at random. This is the only objective way to allocate treatments and it ensures that differences between treatments can be estimated free from **bias** (*see Randomization in Experimental Designs*).

Often there are predictable patterns of variation among the experimental units, for example, runs made on the same day can be expected to give more similar responses than runs made on different days or subjects of similar ages can be expected to give more similar responses than subjects of greatly different ages. By identifying these predictable patterns of variation, we can aim to ensure that the treatments can be assessed by comparing the effect of different treatments run on the same day, rather than on different days. This allows more precise **estimation** of the differences between treatments. In the pastry dough experiment, only four runs could be made per day, so that two blocks, each of four runs, were used.

In order to be useful, blocks have to be chosen so that units within each block are expected to give similar responses; but formally, blocking is defined as a form of restricted **randomization**. In a *completely randomized design*, given a treatment design (i.e., the treatments and the number of replicates of each) and a set of experimental units, the treatments are assigned to the experimental units completely at random (*see Randomization in Experimental Designs*). In a *randomized block design* the randomization is restricted, so that the treatments in a specific block are allocated to the units in that block completely at random, with the randomization being done independently for each block. Thus we need to decide not just the replication of each treatment, but also the allocation of treatments to blocks. In the example, after defining which four treatments would go in each block, the order of the blocks was selected at random and then the run order within each block was selected at random.

Note that the formal definition of blocking does not imply a good way to choose blocks for a specific experiment. In order to be successful, the units within the same block must give more similar responses than the units in different blocks. Of course, it is not possible before running the experiment to guarantee that this will be true. The statistical theory tells the experimenters that they should try to identify suitable blocks composed of homogeneous units. All the experimenters' prior knowledge, insight, and experience are needed to ensure that a good set of blocks is actually chosen.

In some applications the block size will be very clear, for example if testing is being carried out in a number of different centers on six lines (units) in each center, it is clear that we have blocks of six units each. In many cases, however, there will be some choice as to how many units are in each block, for example if blocks correspond to the runs made on the same day there might be some flexibility over how many runs can be made each day. The usual advice in such situations would be to make the blocks as large as is reasonably practicable, but this must be balanced against the concern that large blocks will compromise the similarity of the units in the blocks, against the danger of being unable to complete the full number of units in a day for example, and against the possible deterioration in experimental technique if experiments are performed too hurriedly. In the example, the experimenter was confident that four

2 Blocking

runs could be made each day, so this was the block size used.

See Mead [1, Chapters 2, 7, and 9], Hinkelmann and Kempthorne [2, Chapters 5 and 9], or other general books on the design of experiments for further discussion of randomization and blocking. Sometimes the experimental units are divided into “blocks”, but the treatments are not randomized to the units within the blocks. In such cases, it is probably advisable to analyze the data as if the experiment had been properly randomized. However, it must be realized that the interpretation of such an analysis is very strongly dependent on the assumption that units within a block are homogeneous and so is much less robust than it would have been had the design been carefully randomized.

Complete Blocks

If we plan to have equal replication of each treatment and if it is sensible to choose the block size to be equal to the number of treatments, then it is possible and advisable to use a *complete block design*, in which each treatment appears exactly once in each block. For example, if our pastry dough experiment had only four treatments, a complete block design is shown in Table 1. Before being used in an experiment, this *combinatorial design* should be randomized, by randomly allocating the treatments to the units in each block independently. The design is now known as a *randomized block design* or more correctly as a *randomized complete block design (RCBD)*. One particular randomization of the combinatorial design of Table 1 is shown in Table 2. Note that for the complete block design, there is no need to randomize the blocks, since each block contains exactly the same set of treatments.

Table 1 Complete block design for four treatments, numbered 1–4, in two blocks

Block	
I	II
1	1
2	2
3	3
4	4

Table 2 Randomized complete block design for four treatments, numbered 1–4, in two blocks

Unit	Block	
	I	II
I	1	1
II	4	3
III	2	2
IV	3	4

The RCBD is relatively easy to set up and to use, and it is very simple to analyze the resulting data. For continuous responses, letting $y_{ij(r)}$ denote the j th unit, $j = 1, \dots, t$, in block i , $i = 1, \dots, b$, with treatment r applied, $r = 1, \dots, t$, the data can be analyzed using the linear model

$$Y_{ij(r)} = \mu + b_i + \tau_r + \epsilon_{ij} \quad (1)$$

where $\sum_{i=1}^b b_i = 0$, $\sum_{r=1}^t \tau_r = 0$ and the ϵ_{ij} are assumed to be independent and to have constant variance σ^2 . The analysis resulting from this model can also be justified by the randomization carried out, assuming only that treatment and unit effects are additive. This model leads to an analysis of variance having the form shown in Table 3, where $n = bt$ is the total number of units (*see Analysis of Variance*).

The variance for estimating any treatment contrast (i.e., any comparison among treatments) from this design is the corresponding variance from a completely randomized design multiplied by σ^2/σ_u^2 , where the subscript u indicates that the variance is from the unblocked design. Thus, as long as the variance between units within blocks is less than the variance between units across blocks, blocking leads to improved estimation. If the blocks do, indeed, form

Table 3 Skeleton analysis of variance for randomized complete block design

Stratum	Source	df
Blocks	Error	$b - 1$
Units	Treatments	$t - 1$
	Error	$n - b - t + 1 = (b - 1)(t - 1)$
	Total	$n - b = b(t - 1)$
Total		$n - 1 = bt - 1$

homogeneous units, the reduction in variance can be very large.

Incomplete Blocks

General Ideas

It is often necessary to use *incomplete blocks*, that is, those that do not contain all treatments. In particular, when using **factorial** treatment structures as in our example, there is usually a large number of treatments and for many practical situations it is advisable to use blocks that are smaller, sometimes considerably smaller, than the number of treatments. Incomplete blocks raise the new problem of how to arrange the treatments into blocks, that is, how to choose which subset of the treatments should be used in each block. Consider a trivial example of three treatments, each replicated twice, in three blocks, each containing two units. The possible arrangements in blocks (up to symmetry) are given in Table 4. In this simple case it is obvious that design 1 is best, since the other designs do not allow a comparison (within blocks) of the treatment labeled 1 with either of the other treatments. Note that the table gives the *combinatorial design*, which simply shows which treatments appear together in blocks. Before being used for a particular experiment, it must be randomized. Randomly reordering the blocks, we get the order (II, I, III). Then we randomly allocate the treatments in each block, obtaining the orders (II, I), (I, II), and (II, I), respectively, giving the plan shown in Table 5. Of course, this randomization must be carried out afresh for each new experiment. However, the properties of the design depend only on the combinatorial design and the method of randomization and not on the outcome of the randomization.

In general, it will be much less obvious what the best design (i.e., arrangement of treatments to blocks) will be, but we try to choose designs which allow for good comparisons between treatments. The

Table 4 Designs for three treatments in blocks of size 2

Design 1 Block			Design 2 Block			Design 3 Block		
I	II	III	I	II	III	I	II	III
1	1	2	1	2	2	1	2	3
2	3	3	1	3	3	1	2	3

Table 5 Design 1 from Table 4 after randomization

Unit	Block		
	I	II	III
I	3	1	3
II	1	2	2

precise meaning of this depends on the objectives of the experiment, which in turn define the treatment structure, the relevant treatment contrasts, and the model for treatments. For example, if the objective is to find the best of several products, we will be interested in direct comparisons of pairs of treatments and should choose a design which minimizes the variances of these comparisons. If, on the other hand, the objective is to optimize the running of some industrial process, we might fit a multifactor polynomial model to the responses and should choose a design that allows the parameters of such a model to be well fitted.

If the design is randomized by randomly permuting blocks and by randomizing treatments to units within each block (independently), then the implied linear model is similar to that for a complete block design,

$$Y_{ij(r)} = \mu + b_i + \tau_r + \epsilon_{ij} \quad (2)$$

Formally, the block effects should be considered as random, giving the linear mixed model

$$Y_{ij(r)} = \mu + \delta_i + \tau_r + \epsilon_{ij} \quad (3)$$

but it usually makes little difference and often the data are analyzed as if the blocks were fixed. The analysis of variance (*see Analysis of Variance*) also takes the same form as for the RCBD, but the variances of particular treatment contrasts depend on how the treatments are allocated to blocks. For some estimated treatment contrasts the variances will be greater than the corresponding variances from a completely randomized design multiplied by σ^2/σ_u^2 . In the analysis with fixed blocks, define the *efficiency factor* E_k for a contrast C_k as

$$E_k = \frac{V_u(\hat{C}_k)/\sigma_u^2}{V(\hat{C}_k)/\sigma^2} \quad (4)$$

so that contrast C_k is better estimated from the blocked design if $E_k > \sigma^2/\sigma_u^2$. Note that all efficiency factors are 1 in a complete block design.

4 Blocking

Efficiency factors of less than 1 represent a loss of information on treatment comparisons. This information is “lost” in the sense that it cannot be obtained from comparisons between units in the same block. If block effects are considered to be random, then this information can be recovered by comparing block totals (or means). The variance relevant for assessing this information is the variance between blocks, which will typically be high, so this *interblock information* is often of little use. However, there are some circumstances, discussed later, under which the interblock information is both useful and necessary for a proper analysis to be carried out. Residual maximum likelihood (REML) analysis is sometimes used to combine the interblock analysis with the usual, intrablock analysis, but this is valid only for large numbers of blocks and can have poor properties in smaller experiments. John and Williams [3, Chapter 7] give a thorough description of interblock information and the combined analysis.

Unstructured Treatments

When the treatments are categories of a single qualitative factor, it is usually the case that the experimenters are equally interested in all pairwise comparisons of treatments, for example, to find the best treatment or simply to check whether there are differences between the treatments. In this case, we should aim to make the design *balanced*, that is, $V(\hat{\tau}_r - \hat{\tau}_s)$ should be equal for all $r, s; r \neq s$. Balanced designs exist only for some specific numbers of treatments, replications, and block sizes.

For equally replicated treatments and blocks of equal sizes, it is easily shown that a design is balanced if all pairs of treatments appear together in blocks equally often. This makes it very simple to find small *balanced incomplete block designs* (BIBDs) when they exist (see **Block Designs, Incomplete**). For example, a BIBD for 6 treatments in 10 blocks each of 3 units is given in Table 6. For larger problems several methods of construction are available and several lists of BIBDs are available, for example, Cochran and Cox [4, Chapter 9] or <http://www.designtheory.org/>.

When no BIBD exists, a nearly balanced design is chosen. However, the definition of nearly balanced is not clear and it is usual to choose a design to optimize a criterion such as A-, D- or E-efficiency (see **Optimal Design**). A design is said to be

Table 6 Balanced incomplete block design for 6 treatments in 10 blocks of 3

I	Block								
	II	III	IV	V	VI	VII	VIII	IX	X
1	1	1	1	1	2	2	2	3	3
2	2	3	4	5	3	4	5	4	4
3	4	5	6	6	6	5	6	5	6

- *A-optimally* blocked if it minimizes the average variance of estimated pairwise comparisons among treatments.
- *D-optimally* blocked if it minimizes the volume of a joint confidence region for the parameters.
- *E-optimally* blocked if it maximizes the minimum efficiency factor for any estimated contrast.
- *M-optimally* blocked if it maximizes the mean of the efficiency factors for pairwise comparisons among treatments.
- *(M,S)-optimally* blocked if it minimizes, among M-optimally blocked designs, the variance of the efficiency factors for pairwise comparisons among treatments.

If it exists, a BIBD optimizes all of these criteria. See John and Williams [3, Chapter 2] for a discussion of these criteria for optimal blocking.

For relatively small designs, it is possible to do a complete search of all possible block designs (see <http://www.designtheory.org/>). For larger designs, a search procedure must be used which will not be guaranteed to find the **optimal design**, but which has a high probability of finding an optimal, or very nearly optimal, design. Such searches are usually based on *interchange algorithms*, which arrange a given treatment design in blocks to optimize the relevant criterion. The general structure of an interchange algorithm is as follows:

1. Randomly allocate the treatments to blocks.
2. If the resulting design allows the model with fixed blocks to be fitted, evaluate the criterion and call this the *current design*. Otherwise, go to 1.
3. Systematically interchange treatments between units in different blocks, calculating the criterion for each design obtained. If the new design is better than the current design, it becomes the current design. Continue until no possible interchange improves the design.

4. The current design is the near-optimally blocked design.

Usually the whole procedure is restarted several times, called *tries*, and the best design from any try is kept. Interchange algorithms for block designs are discussed by Atkinson and Donev [5, Chapters 14 and 15].

Note that the criteria that are commonly optimized are based entirely on the intrablock analysis. This is most appropriate, since the interblock analysis is rarely useful (except as a last resort in trying to obtain information from badly designed experiments).

Factorial Treatments

When the treatments are combinations of levels of several factors as in our example, it is usually not the case that all treatment comparisons are of equal interest (see **Factorial Experiments**). Instead main effects and low-order interactions are usually more important and so the design should be arranged in blocks in such a way that these low-order effects can be well estimated even at the cost of very poor estimation of the higher-order effects. With some regular treatment structures and specific, convenient block sizes, standard designs exist. For example, our treatments are a single replicate of a 2^3 factorial design and there are two blocks of four units each. Then the design in Table 7 allows all main effects and two-factor interactions to be estimated with efficiency factors of 100%, while the three-factor interaction cannot be estimated in the intrablock stratum. The three-factor interaction is said to be *confounded* with block effects.

Note that the design in block I in Table 7 is a fractional factorial design (see **Fractional Factorial Designs**), specifically a half replicate, and the design in block II is the complementary half replicate. If two replicates of the 2^3 treatment set were to be

Table 7 Single replicate of a 2^3 treatment set in two blocks of four units

Block I			Block II		
X_1	X_2	X_3	X_1	X_2	X_3

-1	1	1	-1	1	-1
1	-1	1	1	-1	-1
1	1	-1	1	1	1

used, we can confound the three-factor interaction in one replicate and a two-factor interaction in the other replicate, as in Table 8, where the two-factor interaction X_2X_3 is confounded in blocks III and IV. In the overall design, the effects X_2X_3 and $X_1X_2X_3$ can each be estimated with an efficiency factor of 50% and are said to be *partially confounded* with block effects.

Note that the information that is lost can be recovered in the interblock analysis, but that these effects will usually be estimated with high variance. For example, the analysis of variance for the design in Table 8 has the form shown in Table 9. A design with one or more main effects confounded with blocks is known as a *split-plot* design (see **Split-Plot Designs**). Mead [1, Chapter 15], Hinkelmann and Kempthorne [2, Chapter 11], and many other books on design of experiments describe confounding in more detail. Tables of standard confounded designs can be found in Cochran and Cox [4, Chapter 6] and Wu and Hamada [6, Chapter 3].

The theory of confounding extends to fractional factorial treatment sets (see **Fractional Factorial Designs**). For example, the resolution V (see **Factorial Designs, Resolution of**) half replicate of the 2^5 design with defining contrast $-X_1X_2X_3X_4X_5$ can be arranged in two blocks by confounding the two-factor interaction X_4X_5 . This automatically confounds this effect's alias, the three-factor interaction $X_1X_2X_3$ (see **Aliasing in Fractional Designs**). The design is given in Table 10. Again, published tables of these regularly confounded designs are available, for example, Wu and Hamada [6, Chapters 4 and 5], and

several comprehensive statistical programs include general routines for constructing regular confounded designs. Recent work on confounded fractional factorial designs includes Zhu [7], Cheng and Tang [8], and Butler [9].

If the treatment design is not equally replicated, is an irregular fraction, or is chosen to be able to fit a polynomial model, or if the block sizes are such that no regular design exists, it is necessary to use a search procedure. This situation also arises if the “blocks” are individual stages in a sequential design (*see Sequential Experimentation*). Again, for small problems a complete search might be possible, but otherwise an interchange algorithm will be used. This works exactly as for unstructured treatments, except that slightly different optimality criteria will

Table 10 Half replicate of a 2^5 treatment set in two blocks of eight units

1	1	−1	1	1	1	1	1	1	−1

be appropriate (*see Optimal Design*). It is usually necessary to specify a model and then arrange the design in blocks to optimize some function of the variance matrix of the parameter estimates. Useful optimality criteria include the following:

- *weighted-A-efficiency*, which minimizes a weighted average of the variances of the parameters of interest;
- *D-efficiency*, which minimizes the volume of a joint confidence region of the parameters of interest;
- *E-efficiency*, which maximizes the minimum efficiency factor among the parameters of interest; and
- *weighted-M-efficiency*, which maximizes a weighted mean of the efficiency factors of the parameters of interest.

A-efficiency is sometimes defined without weights, but this definition is scale dependent (e.g., if the coding of factor levels is changed, the definition of the criterion changes), and so should not be used without making clear what the scale is. Cook and Nachtsheim [10], Atkinson and Donev [11], Trinca and Gilmour [12], and Goos [13, Chapter 2] discuss algorithms for blocking in more detail.

Extensions

The idea of blocking can be extended to situations in which there is more than one blocking factor, that is, there is more than one way of defining sets of units which can be expected to be similar and the randomization is restricted to allow for all of them.

The first possibility is *nested* blocking factors, in which the units are grouped together in blocks and the blocks themselves are grouped into superblocks. For example, if the units are runs of a process and the blocks are days, then it might be that the

Table 11 A 4×4 Latin square

Row	Column			
	I	II	III	IV
I	1	2	3	4
II	2	3	4	1
III	3	4	1	2
IV	4	1	2	3

experiment is run on four days, two consecutive days and then, somewhat later, another two consecutive days. In such a case, it is often sensible to restrict the randomization of blocks to days in such a way that a good design is obtained with respect to the superblocks. For example, the blocks in Table 8 can be grouped into two superblocks, one containing blocks I and II and one containing blocks III and IV. In this case, each superblock contains a single replicate of each treatment and the design is said to be *resolved* (often only *resolvable* designs, i.e., those that can be resolved, are defined, but this is a purely mathematical concept). The idea of nesting can, of course, be generalized to any number of levels, but it is unusual to have more than three strata, except in generalizations of split-plot designs (see **Split-Plot Designs**) in which the main effects of different factors are confounded at different strata. Bailey [14] and Gilmour and Trinca [15] discuss nested block designs further.

Another possibility is *crossed* blocking factors, in which the units are grouped into two sets of blocks, often called *rows* and *columns*, so that each row-column combination contains a unit. For example, a study of process operating conditions might involve several runs made each day with each run made by a different operator, so that days are rows and operators are columns. Then a design should be chosen which is a good block design with respect to rows and a good block design with respect to columns. If the numbers of rows and columns are both equal to the numbers of treatments, then a *Latin square* can be used, for example, the 4×4 Latin square shown in Table 11 is a design for comparing four treatments in four rows and four columns (see **Latin Squares and Related Experimental Designs**). For factorial designs, confounding techniques can be used for some sizes of rows and columns, but in general a search algorithm will be needed. The idea of crossing can also be extended to more than two blocking factors, but this is unusual in practice. Algorithms for crossed blocking are described by Gilmour and Trinca [16].

STEVEN G. GILMOUR

Computer Experiments

Introduction

Investigators in virtually all areas of science and engineering application have become dependent on *computer models* as tools in designing, testing, and evaluating physical systems. The physical systems of interest range from manufacturing supply chains to complex chemical reactions to the global climate. Computer models can be based on theoretical knowledge of the physical system of interest, empirically derived relationships, or both. In any case, they are computer programs that evaluate or solve mathematical equations written to describe the physical system of interest. Hence a global climate model is a program written to simulate or predict climate patterns years or centuries in the future, on the basis of specified *initial conditions* representing the state of the climate system at the beginning of simulated time and *forcing functions* representing possibly changing aspects of natural and man-made influences on the system.

Because these models are often quite complex, their behavior can sometimes be surprising, even to their authors. Hence empirical studies based on the model, or *computer experiments*, may be performed for a number of purposes. The phrase “computer experiment” is intended to suggest an activity similar in many ways to traditional experimentation, but where the computer model is (at least one of) the object(s) of interest. Following standard experimental language, *treatments* correspond to the values selected for model inputs or other quantities that must be specified before the model can be evaluated or “run”, and *observations* correspond to the values of the outputs, or summary functions of them, resulting from such runs. *Experimental design* in this context primarily involves the selection of input vectors or specific model runs to be included in the experiment. As with traditional or *physical* experiments, the overall goal of a computer experiment is generally the collection of information that will support an empirical understanding of the relationship between inputs and outputs.

While it is useful to view computer experiments and physical experiments as similar, there are important differences. One of these differences is the treatment of experimental error. Deterministic

computer models produce exactly the same output values if run multiple times under the same conditions. This means that the usual emphasis on replication, **randomization**, and **blocking** in physical experiments is not relevant in computational studies. (An important exception is with computer models, such as discrete-event simulators, that include stochastic simulation as part of the calculation; replication often *does* make sense in studying these models.) Another important difference is the large dimension of the input and output vectors in many computer models. It is not unusual for computer experiments to involve tens, hundreds, or even thousands of input and/or output variables, while most physical experiments (except perhaps in certain screening contexts) involve far fewer factors and responses.

Categories of Computer Experiments

The reasons for performing computer experiments are as many and as varied as the reasons for performing physical experiments. In this section, three general categories of computer experiments are briefly described. The first two correspond to what might be called *factor screening* and *follow-up studies*, respectively, in a physical experiment context. The third category involves joint consideration of the model and the physical system it mimics.

Assessment of the Relative Importance of Inputs

As with experimental programs in physical contexts, one early goal is to identify the factors/inputs that are most important in determining the values (or changes in values) of the outputs. This is perhaps even more critical in computer experiments, due to the very large number of input variables often encountered. One popular experimental paradigm is based on the assignment of a probability distribution to the input vector and the selection of input values through restricted random processes designed to allow **estimation** of characteristics of the resulting distribution of outputs. This exercise can be thought of as an empirical “transformation of variables” problem and is often performed to identify how much of the propagated variance might be eliminated by reducing uncertainty in each individual input or in groups of related

2 Computer Experiments

inputs. These techniques are often referred to as *sensitivity analysis* or *uncertainty analysis*; several of them are described in [1], along with case studies from a number of application areas. Other methods, which might be called *quasi-modeling*, are based on using rank-transformed data in traditional linear regression or **correlation** analyses; ranks are used to linearize monotonic relationships between inputs and outputs, for example [2]. Group screening ideas have also been used in computer experiments, usually in sequential form, to efficiently identify those inputs that require more intensive follow-up, for example [3].

Quantitative Understanding of a Computer Model

After the subset of most influential inputs has been identified, experimental emphasis often progresses to a more detailed investigation of how these inputs affect outputs. Construction of an approximation to the model function, sometimes called a *metamodel* or *surrogate*, is often desirable at this point, to facilitate rapid output approximations for applications that require a large number of output values (e.g., **Monte Carlo** studies in which the computer model is evaluated inside the simulation loop), or to produce a simpler functional form to aid in understanding the model. A series of such model surrogates is used as the basis of an optimization procedure in [4], with an application involving the design of a helicopter rotor blade. Linear regression models have sometimes been used for this purpose; an early contribution [5] describes extended **central composite** designs for third-order polynomial models and demonstrates their use in a computer experiment. However, much of the statistical research in recent years has focused on the use of Gaussian process models, similar to the Kriging models used in geostatistics, rather than traditional linear models, for example [6] and [7]. Gaussian process models have generally preferable properties as metamodels for deterministic computer models because they can be easily constructed to interpolate (rather than smooth) the noiseless output data, and are much more flexible (and so can more faithfully reproduce nonlinear and asymptotic behavior) than traditional regression models. Excellent detailed references for the use of Gaussian stochastic processes in this setting can be found in [8] and [9]. A demonstration of how such models can be used both to screen inputs and to

explore the structure of input–output relationships through functional analysis of variance (**ANOVA effects**), lower-dimensional components of the predicted model function, is given in [10]. Designs for fitting Gaussian process models have been constructed using several criteria including entropy [11] and asymptotically justified distance-based indices [12].

Understanding and Using Relationships between a Model and Its Context

Everything said to this point has emphasized experimental activity directed at understanding the computer model *per se*, rather than the physical system it mimics. Since the latter is the object of ultimate interest, experimental effort eventually moves to studies involving both. For these purposes, suppose the computer model is denoted

$$y = M(\mathbf{x}, \boldsymbol{\theta}) \quad (1)$$

where y is the output of interest, $\mathbf{x}$ is the corresponding vector of inputs, and $\boldsymbol{\theta}$ are model parameters such as physical rate coefficients. In most real applications, many output variables are actually of interest, but we limit this description to a scalar value for simplicity. The model is designed to mimic *reality* where, for example, y_R results from $\mathbf{x}_R$. Computer experiments requiring both physical measurement y_R and model output y may be carried out for the following purposes:

- **Model calibration** – determination of $\boldsymbol{\theta}$ so that y matches y_R as well as possible when $\mathbf{x}$ matches $\mathbf{x}_R$. Joint analysis of physical and model data for calibration is developed in [13] and demonstrated using computer models of a charged particle accelerator and a spot welding process.
- **Model validation** – for a calibrated model, determination of how well y matches y_R when $\mathbf{x}$ matches $\mathbf{x}_R$. A validation study involving CORSIM, a traffic simulation model, using physical traffic data collected in an urban setting is reported in [14].
- **Inverse problems** – for a calibrated and validated model, determination of $\mathbf{x}$ leading to $y = y_R$ when $\mathbf{x}_R$ is unknown. A Gaussian stochastic process is used in [15] to make inference about the initial conditions ($\mathbf{x}$) leading to specified

observations (y) in a one-dimensional fluid flow problem.

These descriptions have been overly simplified for illustration; in each case, single unique solutions generally are not available and uncertainty characterization is critical.

Experiments involving both model outputs and physical data generally must account for the fact that computer models are not perfect representations of reality. In [16], a metamodel for the computer model and an estimate of the “discrepancy function”, or difference between y and y_R as a function of $\mathbf{x}$, are simultaneously constructed. This approach can also be used for the joint analysis of multiple computer models of a common physical system. The broader problem of combining data from computer models, physical experiments, and **expert opinion** in a unified analysis is considered in [17].

Gaussian Process Models

As noted in previous section, much of the most recent work in the design and analysis of computer experiments is based on the use of a Gaussian stochastic process model as a statistical surrogate for the computer model. (See, e.g., [8] or [9] for a detailed treatment of these models.) Continuing with the notation of previous section, the output y is modeled *a priori* as a *random function*, normally distributed at each $\mathbf{x}$ and jointly multivariate normal at any collection of $\mathbf{x}$'s, and characterized by functional representations of the mean and variance:

$$\begin{aligned} E(y(\mathbf{x})) &= \mu(\mathbf{x}), \quad V(y(\mathbf{x})) = \sigma^2(\mathbf{x}), \\ \text{Cov}(y(\mathbf{x}), y(\mathbf{x}')) &= C(\mathbf{x}, \mathbf{x}'), \quad \mathbf{x}, \mathbf{x}' \in \Delta \end{aligned} \quad (2)$$

where Δ is the space of allowable values of the input vector. In practice, the second-order **moments** are usually assumed to be stationary, and the mean function often is as well:

$$\begin{aligned} E(y(\mathbf{x})) &= \mu, \quad V(y(\mathbf{x})) = \sigma^2, \\ \text{Cov}(y(\mathbf{x}), y(\mathbf{x}')) &= \sigma^2 R(|\mathbf{x} - \mathbf{x}'|), \quad \mathbf{x}, \mathbf{x}' \in \Delta \end{aligned} \quad (3)$$

where $|\mathbf{x} - \mathbf{x}'|$ denotes the vector of absolute values of the elements of $\mathbf{x} - \mathbf{x}'$, and $R(-)$ is a *correlation function*. R is often a parameterized function, for example,

$$R(|\mathbf{x} - \mathbf{x}'|) = \exp(-|\mathbf{x} - \mathbf{x}'|^T \Lambda |\mathbf{x} - \mathbf{x}'|) \quad (4)$$

where $\Lambda = \text{diag}(\lambda_1, \lambda_2, \lambda_3, \dots, \lambda_k)$ and k is the dimension of $\mathbf{x}$, is called the *product Gaussian correlation function*, with parameters (λ 's) that control how quickly the positive correlation between output values decreases with distance in each coordinate of the input vector. An experimental design of size N , $D = \{\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \dots, \mathbf{x}_N\}$, is selected, the corresponding runs of the model are executed, and an N vector of outputs $\mathbf{y}_D$ results. For this model and known parameters, the frequentist best linear unbiased predictor (BLUP), or Bayesian prediction based on squared-error loss, of y at a new input vector $\mathbf{x}_0$ is as follows:

$$\hat{y}(\mathbf{x}_0) = \mu + \mathbf{r}_{\mathbf{x}_0, D}^T \mathbf{R}_{D, D}^{-1} (\mathbf{y}_D - \mu \mathbf{1}) \quad (5)$$

where $\mathbf{r}_{\mathbf{x}_0, D}$ is an N vector of correlations, $R(|\mathbf{x}_0 - \mathbf{x}_1|)$, $R(|\mathbf{x}_0 - \mathbf{x}_2|)$, $R(|\mathbf{x}_0 - \mathbf{x}_3|)$, $\dots$, $R(|\mathbf{x}_0 - \mathbf{x}_N|)$, and $\mathbf{R}_{D, D}$ is the $N \times N$ correlation matrix with (i, j) element $R(|\mathbf{x}_i - \mathbf{x}_j|)$. The corresponding **standard error** of prediction, or posterior standard deviation, is

$$\text{se}(\hat{y}(\mathbf{x}_0)) = \sigma \sqrt{1 - \mathbf{r}_{\mathbf{x}_0, D}^T \mathbf{R}_{D, D}^{-1} \mathbf{r}_{\mathbf{x}_0, D}} \quad (6)$$

As noted, these expressions assume that μ , σ^2 , and any parameters of $R(-)$ are known. Simple extensions apply when μ is unknown; for example, the expression for $\hat{y}(\mathbf{x}_0)$ in which $\hat{\mu} = \mathbf{y}_D^T \mathbf{R}_{D, D}^{-1} \mathbf{1} / \mathbf{1}^T \mathbf{R}_{D, D}^{-1} \mathbf{1}$ is substituted for μ in the frequentist BLUP, but this still requires knowledge of the correlation parameter values. Since it is usually not reasonable to regard these parameters as known quantities in practice, fitting a Gaussian process model usually involves estimation of the stochastic process parameters, often by the method of maximum likelihood, or through a more comprehensive Bayesian treatment employing priors on the unknown parameters. In any case, the aim is to provide simple predictions of what y would be at any $\mathbf{x}_0$ required, along with a useful measure of uncertainty for that prediction. For any form of correlation function for which $R(\mathbf{0}) = 1$, the prediction exactly reproduces the output and yields standard errors of zero at the design points. When R is a smooth function of its arguments, predictions and standard errors vary smoothly over other points in the input space. The Gaussian stochastic process model also provides a structure within which good experimental designs can be constructed for settings that require derivation of a simulator of M , for example [11] and [12]. Extensions of the basic theory have also been developed

4 Computer Experiments

for settings in which the output is vector valued [18], derivatives of the output with respect to the inputs are computed [19], ancillary *truncation errors* computed in the numerical solution of model equations are available [20], and multiple computer models of the same physical system are used [21].

Experimental Design

As noted above, the design component of a computer experiment often is mainly concerned with the selection of input vectors specifying N runs of the computer model. Perhaps the most popular design used is the Latin hypercube (*see* [22], **Latin Hypercube Designs**), which was initially proposed as an input *sampling* plan for probability-weighted output integration, but is also widely used when the primary goal of the experiment is metamodeling (or model approximation). Especially when the planned analysis is based on a Gaussian stochastic process or other “spatial” modeling methodology, experimental designs that are in some sense “space-filling” are natural choices since they offer “local” support to flexible modeling throughout the experimental region. For this reason, various forms of *uniform designs* (*see* **Uniform Experimental Designs**) have also been proposed for computer experiments. By contrast, key properties of traditional experimental designs, such as orthogonality, may not be so important in this context when linear models are not the basis of data analysis. However, **orthogonal array**-based Latin hypercubes described by [23] use orthogonal structure to insure that Latin hypercubes cover low-dimensional subspaces of the experimental region well.

Optimal design arguments specifically formulated for the Gaussian stochastic process model include entropy (or D optimality for prediction throughout Δ) [11], and distance-based criteria such as the *maximin* (*Mm*) *distance criterion* which has been shown in [12] to be asymptotically equivalent to the entropy criterion under certain conditions. *Mm*, which stipulates that the closest pairs of design points should be as far apart as possible and that the number of point pairs in the design separated by this minimum distance should be minimized, is also intuitively appealing for computer experiments due to the spatial characteristics. The *Mm* criterion has also been used to generate designs within attractive classes, for example, Latin hypercubes [24].

Integrated mean square error of prediction has also been used as an optimality criterion for the construction of designs [25, 26]. A more detailed review of experimental designs for computer experiments is offered in [9].

A Brief Example

Mitchell and Morris [27] presented data from a computer experiment carried out to demonstrate Gaussian process modeling methodology, using a model of methane combustion developed by Frenklach and Rabinowitz [28]. For this demonstration, the output response of interest is the logarithm of ignition delay in the modeled system. The experimentally controlled model inputs are seven reaction rates of interest; the ranges of the reaction rates were determined by physical knowledge of the system, and each was transformed to the unit interval for this exercise. A design of 50 input vectors was selected from the points on a full five-level **factorial** point set, $\{0, \frac{1}{4}, \frac{1}{2}, \frac{3}{4}, 1\}^7$, using a *maximum entropy* criterion associated with the Gaussian process model, essentially finding the design for which the determinant of $\mathbf{R}_{D,D}$ is maximized. Note that this requires specification of the form and parameters of the spatial correlation function. For reasons described in the paper, the authors used a product exponential correlation function:

$$R(\|\mathbf{x} - \mathbf{x}'\|) = \exp(-\mathbf{1}^T \mathbf{\Lambda} \|\mathbf{x} - \mathbf{x}'\|), \quad \mathbf{\Lambda} = 4.6 \times \mathbf{I} \quad (7)$$

as the basis of computing an experimental design. That design, along with the 50 response values computed from the corresponding runs of the computer model, are listed in Table 1.

With the data in hand, the authors used a *piecewise cubic correlation* function described in [7] for model fitting and prediction. In this reanalysis, a Gaussian correlation function was assumed, leading to maximum likelihood estimates of the correlation parameters:

$$\begin{aligned} \hat{\lambda}_1 &= 0.085, \hat{\lambda}_2 = 0.024, \hat{\lambda}_3 = 0.498, \hat{\lambda}_4 = 0.363, \\ \hat{\lambda}_5 &= 0.347, \hat{\lambda}_6 = 0.167, \hat{\lambda}_7 = 0.090 \end{aligned} \quad (8)$$

These parameter estimates are themselves useful indices of “importance” for each input, because they

represent the rate at which correlation appears to decrease with distance in each dimension of the input space. For example, correlation parameter estimates associated with inputs 3, 4, and 5 are relatively large, suggesting that the output may vary more quickly, or in a more “interesting” fashion, as these inputs are varied.

The nature of the input–output relationship can be investigated more directly by use of plots of $\hat{y}$ as functions of one or more elements of $\mathbf{x}$. Panels 1–7 of Figure 1 each display 20 “traces” of $\hat{y}$, the predicted response plotted as a function of one input for fixed, randomly selected values of the other six inputs. Plots such as these display the general shape of the relationship between each input and the response, and also provide an indication of how much that input “interacts” with the others based on how much the shape of the relationship changes from trace to trace. These plots support our initial impression, based on estimates of the correlation parameters, that reaction rates 3, 4, and 5 are most influential in the determination of ignition delay. A further examination of the joint influence of these three inputs can be made by examining contour plots of the output for pairs of inputs. Panels 8 and 9 of Figure 1 display such joint plots for inputs 3 and 4, and 3 and 5 respectively, with all other inputs fixed at the midpoints of their coded scales (0.5).

The general appearance of the plots in Figure 1 suggests that a quadratic polynomial might also serve as a useful model approximation. A full quadratic polynomial, fitted by **least squares** to these 50 data points, does account for most of the variation in the output values, as indicated by $R^2 = 99.6\%$. **Residuals** from this polynomial fit vary between -0.18 and $+0.11$ (compared to a total data range of 3.53), so within these tolerances, a fitted polynomial may well be a reasonable descriptive approximation of the computer model. On the other hand, the Gaussian process predictor reproduces the 50 data values without error. The standard errors constructed under the Gaussian process model are also reasonable representations of prediction uncertainty, for example, they are exactly 0 at the 50 points where the response is known, and are larger at more “remote” points in the design space. Standard errors of prediction constructed in the linear regression framework have no clear interpretation since they are based on

Figure 1 Graphs displaying the form of $\hat{y}$ from the Gaussian process model as a function of scaled inputs. Panels 1–7: 20 traces of $\hat{y}$ as a function of a single input, each with randomly chosen values of the remaining inputs. Panels 8 and 9: contour plots of $\hat{y}$ as a function of inputs 3 and 4, and 3 and 5, with all other inputs fixed at 0.5

assumptions about random “error” that are not realistic in this context.

Summary and Conclusion

Computer experiments are becoming increasingly important in engineering, industry, and the applied sciences. As physical systems of interest grow more

complex and computing power increases, this trend can be expected to continue. Statistical ideas and methods are critical to the design and analysis of these studies, just as they are in traditional physical experimentation. These methods do not necessarily take exactly the same form in both realms, but the differences in effective methods generally reflect the real differences between the properties of the

data produced in the two kinds of experimentation. While computer experiments often do not involve measurement error and do not require traditional strategies such as blocking and randomization, they often involve much larger input spaces and more complex factor (input) versus response (output) relationships than do most physical experiments. An additional difficulty in computer experiments is the fact that the physical system giving rise to creation of the model is usually the object of real interest, rather than the computer model itself. Effective statistical methods, many based on Gaussian stochastic process models, have been developed for use in computer experiments over the last few decades, and further developments in this area will continue to be an important area of research in the future.

Factorial Experiments

Introduction

Statistically designed experiments have been used to accelerate learning since their introduction by R.A. Fisher in the first half of the twentieth century. Fisher's book, *The Design of Experiments* [1], revolutionized agricultural research by providing methods, now used all over the world, for evaluating the results of small sample experiments [2]. One of Fisher's major contributions was the development of factorial experiments, which can simultaneously study several factors. Such experiments ran completely counter to the common wisdom of isolating one factor at a time, with all other factors held constant. Quoting R.A. Fisher: "No aphorism is more frequently repeated in connection with field trials, than that we must ask Nature few questions, or, ideally, one question, at a time. The writer is convinced that this view is wholly mistaken. Nature, he suggests, will best respond to a logical and carefully thought out questionnaire. A factorial design allows the effect of several factors and interactions between them, to be determined with the same number of trials as are necessary to determine any one of the effects by itself with the same degree of accuracy." [3].

New challenges and opportunities arose when Fisher's ideas were applied in the industrial environment. The opportunity for rapid feedback led G.E.P. Box to develop **response surface** methodology, with new families of designs and a new strategy of **sequential experimentation**. Box's contributions were stimulated by problems that arose during his 8 years of work as a statistician for Imperial Chemical Industries (ICI). The book by G.E.P. Box, W.G. Hunter and J.S. Hunter, *Statistics for Experimenters* [4], has become a classic in the area of design of experiments. Statistically designed experiments are now recognized as essential for rapid learning and thereby, for reducing time-to-market, while preserving high quality and peak performance. We present here a brief review of factorial experiments or statistically designed experiments. We focus mostly, but not exclusively, on factorial designs and cover several areas of applications of such designs.

Factorial designs have been extensively studied in the literature. A partial list of references includes [1, 4–16].

Basic Elements of Factorial Designs

The first step in planning any experiment is to clearly define its goals. The next step is to determine how performance will be assessed. The third step is to list the controllable factors that may affect performance. It is very useful to carry out these steps in a "brainstorming" session, bringing together individuals who are familiar with different aspects of the process under study. Typically, the list of potential factors will be long and often there will be disagreements about which factors are most important. The experimental team needs to decide which factors are indeed the most important, which of those will be systematically varied in the experiment, and how to treat the ones that will be left out. For each factor that is included in the experiment, the team must decide on its experimental range. Some factors may be difficult or impossible to control during actual production or use, but can be controlled for the purpose of an experiment. Such factors are called *noise factors* (see **Robust Design**) and it can be beneficial to include them in the experiment. In general, for an experiment to be considered statistically designed, the following nine issues need to be ascertained (Table 1). Some of these issues, such as those on determination of the experimental array (6) and the number of replications (7), are purely statistical in nature. Some other points deal with basic problem solving and management such as statement of the problem (point 1) and budget control (point 9).

A typical example is reported on by Milman, Sirota and Steinberg [17]. The goal of this experiment was to discover how required safety modifications would affect performance characteristics of a pyrotechnic device. The test results for each experimental unit were summarized in a graph of pressure against time and four characteristics of the pressure profile were important: initial delay time, maximum pressure, time to maximum pressure, and time from 10 to 90% of pressure increase. After some debate, the team decided to include three factors in the experiment: (a) the type of main charge, (b) the type of booster charge, and (c) the type of initiator. Four different main charges were used, along with two booster charges and three initiators. Thus the experiment is a $2 \times 3 \times 4$ factorial, with 24 possible ways to select the booster charge, initiator, and main charge that would go into a unit. The experiment included all 24 of these combinations, with two units of each type.

2 Factorial Experiments

Table 1 Issues for consideration in statistically designed experiments

	Issue	Description
1	Problem definition	Plain language description of the problem, how it was identified, who is in charge of the process/product under consideration
2	Response variable(s)	What will be measured and with what device; how the data will be collected
3	Control factors	What factors can be controlled by the operator, or by design decisions
4	Factor levels	What are the current factor levels and what are the reasonable alternatives
5	Noise factors	What factors cannot be controlled during regular operations, but could be controlled in an experiment, and what factors simply cannot be controlled, but could be observed and recorded
6	Experimental array	What main effects and interactions are of interest. What is the total practically possible number of runs. What is the detection power required against what alternatives. What are the experimental runs
7	Number of replications and order of experimentation	What is the practically possible number of replications per experimental run. In what order will the experimental runs be conducted
8	Data analysis	How will the data be analyzed. Who will write the final report
9	Budget and project control	Who is in charge of the project. What is the allocated budget. What is the timetable. What resources are needed

In general terms, a factorial experiment will involve k factors and the j th factor will be assigned l_j levels in the experiment. The resulting experiment is then said to be an $l_1 \times l_2 \times \cdots \times l_k$ factorial experiment. If several factors have the same number of levels, it is common to combine the common factors in a shorthand notation. For example, an experiment with three factors, each having two levels, and a fourth factor, having three levels, is a $2^3 \times 3$ factorial experiment.

A *full factorial experiment* includes all the possible combinations of the factor levels. The pyrotechnic experiment is an example of a full factorial experiment. As the number of factors increases, a full factorial experiment may be too large to run. Instead, specially selected subsets of the combinations, known as *fractional factorial designs*, may be used (see **Fractional Factorial Designs; Orthogonal Arrays; Plackett–Burman Designs**; Plackett and Burman [18]).

In the pyrotechnic experiment, all the factors are *nominal factors*; that is, they define options that cannot be placed on any ordered scale. Often experiments include factors like temperature, concentration, speed, and so on, which are *numerical* or *quantitative factors*. These factors have levels on a clear mathematical scale. An intermediate case is an *ordinal factor*, whose levels can be ordered from smallest to largest, but are not associated with a mathematical scale. As an example, an experiment on shock absorbers in a car might include “test track” as one

of the factors, with three different test tracks being used. It is not difficult to set up test tracks so that one is clearly the easiest, one the hardest and one is intermediate, but there is no obvious way to quantify how much harder one is than another.

Special considerations may go into choosing the levels of quantitative factors, as we may typically expect that responses will vary smoothly as their levels are changed. Thus, for example, the number and spacing of levels for these factors will affect whether we can represent their relationships to the responses as linear, or if additional terms are needed to capture nonlinear relationships. Selecting levels close together will usually allow a linear fit to work well, but if they are too close, the effect of the factor may not come through at all. Moving the levels further apart will increase the chances of seeing an effect, but might require a nonlinear relationship, which will require adding some intermediate levels for the factor.

Two-Level Factorial Designs

A common experimental design is one with all input factors set at two levels each. These levels are called *high* and *low* or “+1” and “−1”, respectively. A design with all possible high/low combinations of all the input factors is called a *two levels full factorial design*.

If there are k factors, each at two levels, a full factorial design has 2^k runs.

Consider the two-level, full factorial design for three factors, namely the 2^3 design. This implies eight runs (not counting replications or **center point** runs). Graphically, we can represent the 2^3 design by the cube shown in Figure 1. The arrows show the direction of increase of the factors. The numbers “1” through “8” at the corners of the design box reference the “standard order” of runs (see Table 2).

The left-most column of Table 2, numbers 1 through 8, specifies a (nonrandomized) run order called the *standard order*. These numbers are also shown in Figure 1. For example, run 1 is made at the “low” setting of all three factors.

We can readily generalize the 2^3 standard order matrix to a two-level full factorial with k factors. The first (X_1) column starts with -1 and alternates in sign for all 2^k runs. The second (X_2) column starts with -1 repeated twice, then alternates with two in

a row of the opposite sign until all 2^k places are filled. The third (X_3) column starts with -1 repeated four times, then four repeats of $+1$'s, and so on. In general, the i th column (X_i) starts with 2^{i-1} repeats of -1 followed by 2^{i-1} repeats of $+1$. Note that if we have k factors, each at two levels, there will be 2^k different combinations of the levels. In the case $k = 3$, the number of experimental runs is $2^3 = 8$.

Running trials corresponding to all possible factor combinations means that we can estimate all the main and interaction effects. In a 2^3 full factorial design there are three main effects, three two-factor interactions, and a three-factor interaction, all of which appear in the full model as follows:

$$\begin{aligned} Y = & \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 \\ & + \beta_{12} X_1 * X_2 + \beta_{23} * X_2 * X_3 + \beta_{13} X_1 * X_3 \\ & + \beta_{123} X_1 * X_2 * X_3 \end{aligned} \quad (1)$$

From the factorial experiment we calculate the main effects. In general, the effect of factor i is computed as:

$$E_i = \frac{\sum_{h: x_i = (+)} y_h - \sum_{h: x_i = (-)} y_h}{N/2},$$

where $h = 1, \dots, N, i = 1, \dots, k$ (2)

with N being the total number of trials (number of experimental runs $\times$ number of replicates) and $x_i = (+)$, $x_i = (-)$ corresponding to all values of the response variable at the high and low levels, respectively.

A full factorial design allows us to estimate all eight “ β ”-coefficients.

An effect corresponds to an increase of a factor by two units, from -1 to $+1$. The regression coefficient represents an increase in the factor X by one unit, so we have that for the main effects and the regression intercept:

$$\beta_i = \frac{E_i}{2} \text{ and } \beta_0 = \frac{\sum_{h=1}^N y_h}{N} \quad (3)$$

Formulas for computing interactions under a variety of experimental designs and details on other designs are available in **Foldover Designs; Fractional Factorial Designs; Block Designs, Incomplete; Interactions; Latin Hypercube Designs;**

Factorial Designs and Industrial Experiments

We illustrate factorial experiments by a simple full factorial experiment with three factors at two levels each, using an example presented by Kenett and Steinberg [19]. An organization developing, manufacturing and deploying telecommunication equipment faced a major crisis with functional defects in smart phones being reported by sales and marketing. Such reports had a negative effect on sales, and created a potential product recall with dramatic economic consequences. It became critical to quickly focus on the cause of the functional defects so that target actions could be launched in order to contain the growing problem. Management nominated an investigation team consisting of engineers from development and production, quality experts and a statistician. The team studied the problem reports and ascertained that the defects were caused by a reduction in interlayer resistance of a specific hybrid component on the smart phones. After intuitive screening of various factors that could affect the hybrid's performance, it was decided to focus on three nominal factors (a) dielectric type, (b) paste type, and (c) oven.

Production had switched to lower cost dielectric and paste types. Two ovens were used to produce the hybrid components and one of them was located in an area where recent construction projects created dust and other environmental disturbances. None of these changes were originally believed to have a negative impact on the hybrid components. The team decided to verify these assumptions.

A 2^3 full factorial experiment was designed to analyze the impact of these three factors on the resistance of the hybrid microcircuit. The factors' levels were labeled “−1” and “+1” and each experimental run was conducted with five replicates consisting of hybrids manufactured in identical conditions. The response variable, Y , is interlayer resistance measured in ohms. The experiment lasted 1 month with measurements being repeated every week. Table 3 presents results derived at the end of the first week.

A graphical display of the data is shown in Figure 2 as a cube layout with the average response per experimental run indicated at the corners of the cube. The effect of the oven clearly shows up with oven “−1” producing consistently larger resistances than oven “+1”. An interaction between oven and paste is also apparent, with the effect of the paste depending on the oven used.

Main effect plots on the left of Figure 3 connect average responses over different factor level combinations. Again, we clearly see that oven “+1” produced lower resistance. Splitting the main effect of an individual factor, over the levels of another factor, produced interaction plots. The top right corner interaction plot in Figure 3 corresponds to the interaction between oven and paste. Using paste “−1” in oven “−1” gave high resistances; all the other combinations of these two factors were problematic.

Figure 2 Cube plot of hybrid 2^3 full factorial experiment

The main goal of the experiment was to assess the main effects of the three factors and their interactions. From Table 4 we can see that, except for the paste by dielectric interaction, all effects and interactions are significantly nonzero.

In Figure 4, a normal and half-normal probability plot of the main effects and interactions are presented (see **Half-Normal Plot**, [20]). Again only the paste by dielectric interaction appears as nonsignificant. These conclusions allowed management to focus the recall on batches produced in oven “+1” with

dielectric “-1” and contain the problem. The figures and analysis in this example were generated with the MINITAB™ version 15 software.

Factorial Designs in Marketing Applications

Factorial designs are extensively used in marketing applications. Suppose you wanted to book an airline flight and you had a choice of spending \$400 or \$700 for a ticket. If this were the only consideration

Figure 3 Main effect and interaction plots of hybrid 2^3 full factorial experiment

6 Factorial Experiments

Table 4 Effects and coefficients of hybrid 2^3 full factorial experiment

Estimated effects and coefficients for Y (coded units)					
Term	Effect	Coefficient	SE coefficient	T	P
Constant		87.47	1.306	67.00	0.000
Paste	−28.51	−14.25	1.306	−10.92	0.000
Dielectric	70.98	35.49	1.306	27.18	0.000
Oven	−90.01	−45.00	1.306	−34.47	0.000
Paste * dielectric	−2.49	−1.24	1.306	−0.95	0.348
Paste * oven	57.48	28.74	1.306	22.01	0.000
Dielectric * oven	−31.01	−15.50	1.306	−11.87	0.000
Paste * dielectric * oven	8.50	4.25	1.306	3.26	0.003

then the choice is clear: the lower priced ticket is preferable. What if the only consideration in booking a flight was sitting in a regular or extra-wide seat? If seat size was the only consideration then you would probably prefer an extra-wide seat. Finally, suppose you can take either a direct flight which takes 3 h or a flight that stops once and takes 5 h. Virtually everyone would prefer the direct flight. In a real purchase situation, however, consumers do not make choices based on a single attribute like price, comfort, or convenience. Consumers examine a range of features or attributes and then make judgments or trade-offs to determine their final purchase choice. Marketing specialists developed a specific application of factorial designs to these types of problems and labeled it *conjoint analysis*. Conjoint analysis examines feature

trade-offs to determine the combination of attributes that will be most satisfying to the consumer. In other words, by using conjoint analysis a company can determine the optimal features for their product or service. In addition, conjoint analysis will identify the best advertising message by identifying the features that are most important in product choice. Conjoint analysis presents choice alternatives between products/services defined by sets of attributes. This is illustrated by the following choice: would you prefer a flight with regular seats, that costs \$400 and takes 5 h, or a flight which costs \$700, has extra-wide seats and takes 3 h? Extending this, we see that if seat comfort, price and duration are the only relevant attributes, there are potentially eight flight choices (see Table 5).

Figure 4 Normal and half-normal probability plot of main effects and interactions

Table 5 Factorial design used in conjoint analysis

Choice	Seat comfort	Price	Duration
1	Extra-wide	\$700	5 h
2	Extra-wide	\$700	3 h
3	Extra-wide	\$400	5 h
4	Extra-wide	\$400	3 h
5	Regular	\$700	5 h
6	Regular	\$700	3 h
7	Regular	\$400	5 h
8	Regular	\$400	3 h

Given the above alternatives, product 4 is very likely the most preferred choice while product 5 is probably the least preferred product. How the other choices are ranked is determined by what is important to that individual. Conjoint analysis can be used to determine the relative importance of each attribute, attribute level, and combinations of attributes. If the most preferable product is not feasible for some reason (perhaps the airline simply cannot provide extra-wide seats and a 3-h arrival time at a price of \$400) then the conjoint analysis will identify the *next* most preferred alternative. If you have other information on travelers, such as background demographics, you might be able to identify market segments for which distinct products may be appealing. For example, the business traveler and the vacation traveler may have very different preferences which could be met by distinct flight offerings.

In evaluating products, consumers will always make trade-offs. A traveler may like the comfort and arrival time of a particular flight, but reject purchase owing to the cost. In this case, cost has a high *utility* value. Utility can be defined as a number which represents the value that consumers place on an attribute. In other words, it represents the relative “worth” of the attribute. A low utility indicates less value; a high utility indicates more value. For more on conjoint analysis see [21–24]. Factorial designs have been widely implemented in the social sciences and many other disciplines (see Winer [7]).

Factorial Designs and Statistical Education

A major challenge in teaching statistics is to convey how statistics is used in solving real problems. Introductory courses often fail to provide students with a sense of how to apply statistical ideas. Students,

on the other hand, often complain that introductory statistics courses are a dry encounter with pages of formulas. Factorial designs have been successfully incorporated in such courses to overcome these difficulties [25–27].

Factorial Designs and Clinical Trials

Factorial designs are also used in **clinical trials**. Quoting the US Food and Drug Administration (FDA) guidance to industry on statistical principles for clinical trials: “In a factorial design, two or more treatments are evaluated simultaneously through the use of varying combinations of the treatments. The simplest example is the 2×2 factorial design in which subjects are randomly allocated to one of the four possible combinations of two treatments, A and B. These are: A alone; B alone; both A and B; neither A nor B. In many cases, this design is used for the specific purpose of examining the interaction of A and B. The statistical test of interaction may lack **power** to detect an interaction if the **sample size** was calculated based on the test for main effects. This consideration is important when this design is used for examining the joint effects of A and B, in particular, if the treatments are likely to be used together. Another important use of the factorial design is to establish the dose-response characteristics of the simultaneous use of treatments C and D, especially when the efficacy of each monotherapy has been established at some dose in prior trials. A number, m , of doses of C is selected, usually including a zero dose (placebo), and a similar number, n , of doses of D. The full design then consists of $m \times n$ treatment groups, each receiving a different combination of doses of C and D. The resulting estimate of the response surface may then be used to help identify an appropriate combination of doses of C and D for clinical use” [28].

In Barnett *et al.* [29], a clinical trial with a factorial design is presented. Five hundred and eighty-five patients with threatened stroke were followed in a randomized clinical trial for an average of 26 months to determine whether aspirin or sulfinpyrazone, singly or in combination, influences the subsequent occurrence of continuing transient ischemic attacks, stroke or death. Eighty-five subjects suffered a stroke, and 42 died. Aspirin reduced the risk of continuing ischemic attacks, stroke or death by 19% and

also reduced risk for the “harder”, more important events of stroke or death by 31%, but this effect was sex-dependent: among men, the risk reduction for stroke or death was 48%, whereas no significant trend was observed among women. For sulfinpyrazone, no risk reduction of ischemic attacks was observed, and the 10% risk reduction of stroke or death was not statistically significant. No interaction (i.e., synergism or antagonism) was observed between the two drugs. The authors conclude the analysis of this full factorial experiment with a statement that aspirin is an efficacious drug for men with threatened stroke [29].

Computer Intensive Methods and Factorial Designs

In analyzing data from factorial experiments an underlying model is fitted to the data. Two-level factorial experiments are used to estimate parameters of a linear model which, in turn, depends on the estimability properties of the experimental design. When a model is misspecified, an error of the third kind is said to have occurred. Bootstrapping can be used to flag errors of the third kind or, alternatively, validate a specific model. Use of an inadequate model will often lead to an overestimate of the residual variance and to inflated standard errors for the model parameters. Comparison of **bootstrap** standard errors (SEs) to those from a regression analysis is therefore a valuable diagnostic. If the bootstrap standard errors are clearly smaller than those from fitting a regression model to the experimental data, this is a likely sign that the model is inadequate [30].

In recent years, computer simulators have become an increasingly popular platform for running experiments in the product and/or process development process [31]. Some of the issues involved in computer experiments (*see Computer Experiments*) are common to physical experiments such as the need to study many factors, to make effective local approximations to input–output relationships and to exploit sequential methods. New issues have also arisen: the ability to use a very large number of factor settings, the lack of “experimental error”, the need to combine computer and lab or field data, to name a few. These new issues have stimulated the development of new statistical methods, which are often given the acronym DACE, for the design and analysis of computer experiments, the

title of a milestone publication in this area [32]. Computer simulations provide a platform to running experiments so as to simultaneously optimize and robustify products and processes. The experiments conducted in this context are extensions of the basic factorial experiments. These extensions include space filling experiments such as Latin hypercube (*see Latin Hypercube Designs*), uniform (*see Uniform Experimental Designs*) and lattice designs. For an implementation approach of these techniques, labeled the *stochastic emulator strategy*, see [33].

Computer simulations are used nowadays to study a wide range of phenomena, from automobile performance in crash tests to the impact of chemical mixtures on process yields and integrated circuit design on product performance. Actual physical experimentation in the laboratory or test bed can today be replaced with a “virtual” experiment in which a computer runs a program that simulates the behavior of the true process. Experiments can be run on a simulator at a much faster rate than in the laboratory, allowing companies to dramatically reduce the time, cost and effort needed to conduct experiments. Moreover, process settings that might have been thought risky or even potentially dangerous can easily be tested. When the physical testing is destructive, computer simulations are obviously much more economical than actual experiments.

Foldover Designs

Introduction

Fractional factorial designs are frequently used in the design of experiment area (see **Fractional Factorial Designs**). One consequence of using a fractional factorial design is the **aliasing** of the factorial effects. Consider a 2^{7-4} example given in Montgomery [1], in which a human performance analyst studied eye focus time. Seven two-level factors chosen for study were acuity or sharpness of vision (factor 1), distance from target to eye (factor 2), target shape (factor 3), illumination level (factor 4), target size (factor 5), target density (factor 6), and subject (factor 7). Factors 1–3 constitute a full factorial design with eight runs and are called *basic factors*. The other four factors are defined by *generators* (see **Fractional Factorial Designs**): $4 = 12$, $5 = 13$, $6 = 23$, and $7 = 123$, and are called *generated factors*. The *defining relations* (see **Fractional Factorial Designs**) are given by:

$$\begin{aligned} I &= 124 = 135 = 236 = 1237 = 2345 = 1346 \\ &= 347 = 1256 = 257 = 167 = 456 = 1457 \\ &= 2467 = 3567 = 1234567 \end{aligned} \quad (1)$$

The analysis of the experiment shows that main effects of factors 1, 2, and 4 are significant. However, since each **main effect** is fully aliased with some interactions (e.g., from equation (1), factor $1 = 24 = 35 = 67 = \dots$), it was not clear from the original design whether main effect 1 or two-factor interaction 24 (or 35) was significant. A standard follow-up strategy to break the aliasing of effects is to add a *foldover design* (or simply, *foldover*) by reversing the signs of one or more columns of the initial design. (See, e.g., Box *et al.* [2]; Kutner *et al.* [3]; Montgomery [1]; and Wu and Hamada [4]). Following Li and Lin [5], we denote a foldover plan γ by the collection of columns whose signs are reversed in the foldover design. Then in the eye focus time example, there are $2^7 = 128$ foldover plans to generate a foldover design.

We refer to the *combined design* as the combination of the initial design and its foldover design. When a foldover is added to the initial design, then the resulting combined design will have a better design structure than the initial design. Different

foldover methods are discussed in the next section. Throughout the article we focus on foldover of two-level designs.

Foldover Methods

Foldover on All Columns

A classic foldover approach is to reverse the signs of all columns. This special type of foldover plan is called a *full-foldover* plan in Li and Lin [5]. The resulting full-foldover design for the eye focus example is given in the second part of Table 1. The full-foldover plan has been among the most popular foldover techniques. A main advantage of the full-foldover plan is that any odd-length words in the defining relation of the initial designs do not appear in the combined design. Consequently, if the initial design is of resolution III, the combined design using the full-foldover is of at least resolution IV because all words of length 3 of the initial design disappear in the combined design. (For definitions of *word length* and *resolution* of a fractional factorial design, see **Fractional Factorial Designs** and **Minimum Aberration**.)

To see why this happens and how the use of foldover can untangle aliased effects, consider the eye focus time example. After the initial design was performed, the main effect of factor 2 – the largest among seven main effects – can be calculated as follows:

$$\begin{aligned} l_2 &= \frac{1}{4}(-y_1 - y_2 + y_3 + y_4 - y_5 - y_6 + y_7 + y_8) \\ &= 38.375 \end{aligned} \quad (2)$$

Assuming negligible interactions between three or more factors, we obtain from equation (1):

$$2 = 14 = 36 = 57 \quad (3)$$

Thus,

$$l_2 = 38.375 \rightarrow 2 + 14 + 36 + 57 \quad (4)$$

where the notation means that this contrast is actually estimating the main effect of factor 2 plus the sum of the three two-factor interactions. In the full-foldover design given in the second part of Table 1, factors are denoted by -1 , -2 , -3 , -4 , -5 , -6 , and -7 . It can be shown that it has generators: $4 = -12$, $5 =$

2 Foldover Designs

Table 1 Initial and foldover designs for the eye focus time experiment

Run	Initial design							Response
	1	2	3	4 = 12	5 = 13	6 = 23	7 = 123	
1	–	–	–	+	+	+	–	85.5
2	+	–	–	–	–	+	+	75.1
3	–	+	–	–	+	–	+	93.2
4	+	+	–	+	–	–	–	145.4
5	–	–	+	+	–	–	+	83.7
6	+	–	+	–	+	–	–	77.6
7	–	+	+	–	–	+	–	95
8	+	+	+	+	+	+	+	141.8

Run	Foldover design (on all columns)							Response
	–1	–2	–3	–4	–5	–6	–7	
9	+	+	+	–	–	–	+	91.3
10	–	+	+	+	+	–	–	136.7
11	+	–	+	+	–	+	–	82.4
12	–	–	+	–	+	+	+	73.4
13	+	+	–	–	+	+	–	94.1
14	–	+	–	+	–	+	+	143.8
15	+	–	–	+	+	–	+	87.3
16	–	–	–	–	–	–	–	71.9

–13, 6 = –23, and 7 = 123. We estimate the main effect for factor 2 in the foldover design by

$$l'_2 = \frac{1}{4}(y_9 + y_{10} - y_{11} - y_{12} + y_{13} + y_{14} - y_{15} - y_{16})$$

$$= 37.725 \rightarrow 2 - 14 - 36 - 57 \quad (5)$$

Overall, the main effect for factor 2 can be estimated from the combined 16-run design:

$$\frac{1}{2}(l_2 + l'_2) = \frac{1}{2}(38.375 + 37.725)$$

$$= 38.05 \rightarrow 2 \quad (6)$$

Note that the main effect for factor 2 is “de-aliased” from interactions 14 + 36 + 57 by equations (4) and (5). In fact, all defining words of length 3 in equation (1) do not appear in the defining relations for the combined design. Consequently, all main effects are de-aliased from two-factor interactions.

Foldover on One Column

This type of foldover design was first discussed in [2]. If a foldover on one column is added, then neither this factor nor its associated interactions are aliased with other effects. For example, in the eye focus time

experiment, the largest effect obtained from the first set of eight runs was factor 2. Therefore, it might have been argued that it would be desirable to use a foldover to de-alias factor 2 and all the interactions of other variables with 2.

To see why this could have been achieved by adding a foldover design that switches the sign of column 2 only, we write down the defining relations for the foldover design:

$$I = -124 = 135 = -236 = -1237 = -2345$$

$$= 1346 = 347 = -1256 = -257 = 167 = 456$$

$$= 1457 = -2467 = 3567 = -1234567 \quad (7)$$

From equations (1) and (7), the defining relations for the combined design are as follows:

$$I = 135 = 1346 = 347 = 167$$

$$= 456 = 1457 = 3567 \quad (8)$$

Note that none of the defining words in equation (8) is associated with factor 2.

Optimal Foldover Designs

For many years the traditional foldover approaches have been focused on the foldover on all columns

or just one particular column. Obviously, a foldover can be conducted on *any* set of columns. There has been resurgent research on foldover designs in recent years, after the optimal foldover was considered by Li and Mee [6] and Li and Lin [5]. The former [6] provides a sufficient condition for the situation where a better foldover plan exists compared with the full-foldover plan. The other paper [5] obtains optimal foldover designs for commonly used two-level fractional factorial designs with 16 and 32 runs. Both papers demonstrate that foldover on only a subset of all columns can be a better choice in terms of commonly used criteria, such as the minimum **aberration** criterion. (For the definition of *aberration*, see **Fractional Factorial Designs**.)

In the next section we introduce recent work on optimal foldover designs.

Optimal Foldover

Optimal Foldovers on Two-Level Fractional Factorial Designs

Two-level fractional factorial designs are among the most widely used experiments. Early works on foldover had been focused on these designs. For example, it was well known and stated in many textbooks on design of experiments [1–4] that adding a full-foldover of a resolution III design will result in a combined design that is of resolution IV. However, more recent research [5] shows that the conventional full-foldover approach does not necessarily produce the best combined design in terms of the aberration criterion.

Example 1: Suppose a 16-run design d is defined by: $5 = 12$ and $6 = 134$. This is a resolution III design, and its *word length pattern* (see **Fractional Factorial Designs**) is given by: $W(d) = (0, 0, 1, 1, 1, 0)$. If the full-foldover plan is used, that is, $\gamma = \{1, 2, 3, 4, 5, 6\}$, then the combined design is a resolution IV design, whose word length pattern is $W = (0, 0, 0, 1, 0, 0)$.

We know from [5] that the optimal foldover plan for this initial design is $\gamma^* = \{5, 6\}$. That is, if the foldover design is obtained by switching the signs of columns 5 and 6 only, then the combined design has the best aberration criterion value. Its word length pattern is $W = (0, 0, 0, 0, 1, 0)$, so that it is a resolution V design.

Using a computer search method, Li and Lin [5] obtained and tabulated optimal foldover plans for all 16-run and selected 32-run fractional factorial designs. They also proved that every foldover plan is equivalent to a *core foldover plan*, which involves only the generated factors. For example, for the design defined by $5 = 12$, $6 = 134$, there are only four core foldover plans: $\{0\}$, $\{5\}$, $\{6\}$, $\{5, 6\}$. (Following [5], we use $\{0\}$ to refer to the case where no column is chosen for sign reversal and include it as a core foldover plan.) Then all $2^6 = 64$ foldover plans are equivalent to one of the four core foldover plans. It is easy to see that use of core foldover plans results in substantial computational savings.

Optimal Foldovers on Two-Level Nonregular Designs

Fractional factorial designs are constructed through defining relations (e.g., those given in equation (1)). These designs are called *regular designs*, for which a factorial effect is either orthogonal or fully aliased with any other effect. In contrast, in *nonregular designs* factors are not added by generators and, as a result, some effects are neither orthogonal nor fully aliased, a condition known as being partially aliased (see **Minimum Aberration**). Compared with regular designs, nonregular designs have more complex aliasing structures, but they also provide more flexibility in run size and can be used to entertain more distinct models. For example, all 12-run orthogonal designs are nonregular designs. For two-level designs with 16 runs, both regular and nonregular designs exist. For a given number of factors, there are usually more nonregular designs than regular designs. For instance, among the 55 designs with 16 runs and 7 factors, there are only 6 regular designs and 49 nonregular designs [7].

Several authors discussed properties of foldover of nonregular designs. Both Diamond [8] and Miller and Sitter [9] studied the foldover of 12-run Plackett–Burman designs (see **Plackett–Burman Designs**). For commonly used 12-run and 16-run nonregular designs, Li *et al.* [7] obtained optimal foldover plans, using the generalized aberration criterion proposed by Deng and Tang [10] (see **Minimum Aberration**). Using an indicator function approach, Li *et al.* [7] defined generalized word length, which does not have to be an integer. The *generalized word length pattern* (see **Minimum Aberration**), which is also called the extended word

length pattern in [7], and generalized resolution can then be obtained for a nonregular design.

Li *et al.* [7] proved that the full-foldover plans are optimal for all 12-run and 20-run orthogonal designs in terms of the generalized aberration criterion. Optimal foldover plans for 16-run designs are usually not full-foldover plans. The complete set of optimal foldover plans is given on the web page of an author of [7] (<http://www.csom.umn.edu/~wli>).

Example 2: Consider a 16-run nonregular design d with nine factors. Its generalized word length pattern is: $W(d) = (0, 16; 14, 0; 0, 32; 0, 0)$, having 0 words of length 3, 16 words of length $3\frac{1}{2}$, and so on. A word of length $3\frac{1}{2}$ corresponds to three (out of nine) factors that are partially aliased, with a “correlation” of $1/2$. For the strict definition of a word with fractional length, see [7].

The optimal foldover plan for this design is $\gamma^* = \{9\}$. The generalized word length pattern of the combined design is given by: $W = (0, 0; 14, 0; 0, 0; 0, 0)$. This is a resolution-4 design, compared with a resolution-3.5 initial design d .

Discussion

Foldover design is a useful follow-up strategy. The foldover designs can be easily constructed. Because the resulting combined design is still orthogonal, the analysis is also straightforward. It is especially useful if the initial design is of resolution III and the follow-up experiment is needed to de-alias some main effects and two-factor interactions. In fact, early research on foldover designs such as [2] appeared to be motivated by the fact that adding a full-foldover of a resolution III design produces a resolution IV combined design. Recent studies extend the idea to the foldover on one or two columns [11] and, more generally, to the optimal foldovers on any subset of columns [5–7].

The main weakness of the foldover design is the run-size economy. For a two-level design, a foldover design always requires the *same* run size as the initial design. This can be wasteful if the main purpose of the follow-up experiment is to de-alias a small number of aliased effects. Alternative methods include adding a small optimal design in terms of commonly used criteria such as the D criterion (see **Optimal Design**) or using a Bayesian approach to

design a follow-up experiment, described in Meyer *et al.* [12]. On a related issue, while the foldover method can also be applied to general multilevel factorial designs, the run-size requirement would be an even bigger constraint. Consequently, such foldover designs are less appealing, and most existing studies on foldovers have been focused on two-level designs.

We conclude the article with two remarks. First, the optimal foldover plans described in the last section were obtained using the aberration criterion, where the goal could be to de-alias as many main effects as possible from two-factor interactions or to de-alias as many two-factor interactions as possible from each other. When the foldover design is used for a different purpose (e.g., to de-alias effects involving a specific factor), other foldover plans such as foldover on a specific column may be more appropriate. Second, since foldover design is usually used as a follow-up experiment, it is justifiable to include a **blocking** variable with one level being assigned to the initial design and another level being given to the foldover design. Ye and Li [13] proved that adding such a blocking variable would not change the order of foldover plans in terms of the aberration criterion. Thus, the optimal foldover plans given in [5] and [7], which were obtained without considering the blocking variable, are still optimal when the blocking variable is considered.

Fractional Factorial Designs

Introduction

In a designed experiment that is arranged in a factorial design (*see* **Factorial Experiments**), all possible combinations of the factors' levels are run at least once. For example, a full factorial design with five factors that are each run at three levels would require at least $3^5 = 243$ runs. These designs were originally created for agricultural field experiments, in which typically only one or two experiments could be run each year; each experimental unit (a plot of land) was relatively inexpensive; and the experimenter expected a large amount of unexplained variation. Such experiments are conducive to large factorial designs. However, experiments in research, development, and production in industry are typically characterized by the ability to run many experiments each year; each experimental unit may be relatively expensive; and there is often much less unexplained variation. In such situations, it becomes useful to study a large number of factors with a relatively small number of runs, and this is the purpose of fractional factorial designs. In the situation considered above, only a subset, or fraction, of the 243 combinations would be run in a fractional factorial design.

Suppose we have a set of factors, the number of levels at which each factor will be run, and a run limit of at most n , where n is less than the number of all possible combinations. Then two key questions arise. First, which subset of at most n combinations is "best" to run? Second, what is a good strategy for analyzing the data that result from the experiment?

In industry, it is not uncommon to study seven or more factors in an experiment. To keep the number of runs at a reasonable size, the most common designs are those in which each factor is studied only at two levels, and this will be our primary interest.

Basic Idea of Fractional Factorial Design Construction

Suppose we want to study the effects of four factors, labeled A , B , C , and D , each at two levels, but we can only perform $n = 8$ runs instead of the

$2^4 = 16$ required for a full factorial design. To see the basic idea of constructing a good fractional factorial design in this case, we first consider only three factors, A , B , and C , to form a full factorial (2^3) design, and then add the fourth factor D , to form a fractional factorial design. See the columns labeled **A**, **B**, and **C** in Table 1, where we follow the common practice of listing the factor levels using ± 1 coding. These columns will sometimes be regarded as n -dimensional vectors. (Randomization (*see* **Randomization in Experimental Designs**) of the run order would normally be done as well, but this is not relevant for our discussion.)

For this design, the following is well known:

1. We may estimate the following effects from the data generated by this experiment: the main effects (*see* **Main Effects**) A , B , and C ; the two-factor interactions (*see* **Interactions**) AB , AC , and BC ; and the three-factor interaction ABC .
2. A **main effect**, say of A , may be calculated by the formula $2(\mathbf{A} \cdot \mathbf{Y})/n$, where $\mathbf{Y}$ is the column (vector) of the response data and the " $\cdot$ " denotes the inner-product operator.
3. An interaction effect, say of AB , may be calculated by first defining a new vector $\mathbf{AB}$ that is formed by element-by-element multiplication of $\mathbf{A}$ and $\mathbf{B}$, as shown in Table 1, and then applying the same rule as for a main effect; that is, the AB effect is $2(\mathbf{AB} \cdot \mathbf{Y})/n$.
4. Both theoretically and empirically, the ABC interaction is least likely to have any effect on the results. (This is an example of the *principle of effect hierarchy* – main effects are more likely to be active than two-factor interactions, which in turn are more likely to be active than three-factor interactions, etc.)

Now suppose we want to add the fourth factor, D , but are still limited to $n = 8$ runs. The fundamental strategy in creating this fractional factorial design is to run the levels of D at the same "settings" of the **ABC** column, as shown in Table 1 in the column labeled $\mathbf{D} \equiv \mathbf{ABC}$. When we run the experiment and analyze the data, the effects of D and of ABC cannot be distinguished. We say that they are *aliased* (*see* **Aliasing in Fractional Designs**) or *confounded* with each other. In fact, the effect calculated from this column turns out to be the sum of the D and the

2 Fractional Factorial Designs

Table 1 A 2^3 design augmented to a 2^{4-1} design

A	B	C	AB	AC	BC	D $\equiv$ ABC
-1	-1	-1	1	1	1	-1
1	-1	-1	-1	-1	1	1
-1	1	-1	-1	1	-1	1
1	1	-1	1	-1	-1	-1
-1	-1	1	1	-1	-1	1
1	-1	1	-1	1	-1	-1
-1	1	1	-1	-1	1	-1
1	1	1	1	1	1	1

ABC effects. This is sometimes written as $D + ABC$, where these symbols are used here to refer to the effects of the factors. However, it is very likely that the effect of ABC is either zero or very small, so it is reasonable to claim that any large effect here can be attributed to D .

In summary, one way to consider fractional factorial design construction is (a) start with enough factors (*basic factors*) to run a full factorial design and then (b) add additional factors by confounding them with interactions of the basic factors. An equivalent method would be to begin with a full factorial 2^4 design with factors $A - D$, but only keep those combinations (rows) in which $D \equiv ABC$.

Suppose we want to add a fifth two-level factor, say E , to this eight-run design. From Table 1, we must confound E with either AB , AC , or BC , and here we choose $E \equiv AB$. We are now confounding a main effect with a two-factor interaction instead of a three-factor interaction. Because two-factor interactions are more likely to have an effect than a three-factor interaction, this five-factor design is not as “good” as the four-factor design – if the effect associated with this column turns out to be large, it may often not be clear if the effect is due to E , AB , or a combination of these. We quantify these ideas in the next section.

These types of designs are most commonly known as 2^{k-p} designs. Here, k is the number of factors, the calculated value of 2^{k-p} is the number of treatment combinations, and p , known as the *fractionation element*, determines the fraction 2^{-p} of the number of runs in the design compared to a full factorial. The five-factor example would then be called a 2^{5-2} design – there are five factors, $2^{5-2} = 8$ treatment combinations, and $2^{-2} = \frac{1}{4}$ of the total number of $2^5 = 32$ from the full factorial design were run.

Figure 1 The 2^{5-2} design with $D \equiv ABC$ and $E \equiv AB$

The fractional nature of the 2^{5-2} design we constructed may be seen in Figure 1. That the design is a one-fourth fraction can be seen directly. The figure also shows that E is confounded with AB . For example, at the low level of E , only two of the four combinations of A and B are run; at the high level, only the other two combinations are run. Contrast this with, say, the behavior of A and C with E – at both the low level of E and the high level of E , all four combinations of A and C are run. This means that A , C , and E form a 2^3 design, a projectivity feature (see **Projectivity in Experimental Designs**) of the design. Similarly, if we collapse the design over D and E by combining all four of the “ $A/B/C$ ” cubes, we see that these three factors form a 2^3 design. This should not be surprising, because we started with this design before the addition of factors D and E .

Generators, Defining Contrasts, and Resolution

In the five-factor example, we set $D \equiv ABC$ and $E \equiv AB$. It is more common to write this as $D = ABC$ and $E = AB$, where we treat the symbols here as referring to the columns of ± 1 's. If we perform element-wise multiplication of these columns, we find that $I = ABCD = ABE$, where I , defined to be a column of $+1$'s, is the *identity element* under this column multiplication. We call the two terms

$ABCD$ and ABE the *generators* of the design. It follows that the product of these last two terms is also I , that is $I = ABCD \times ABE = ABCDABE = AABBCDE = IICDE = CDE$. The full set of such terms, $I = ABCD = ABE = CDE$, is called the *defining relation* or the *defining contrast of the design*.

The defining relation is useful because it can be used to find all the confounding in the design. For example, by multiplying all terms in the defining relation by E , we find that $E = ABCDE = AB = CD$. This shows that E is confounded not only with the two-factor AB interaction, which we already knew, but also with the CD interaction. (It is also confounded with the $ABCDE$ interaction, but the effect of this interaction can be safely assumed to be zero.) All the confounding in the design may easily be determined by finding such confounding for I and the basic factors and their interactions. Results for the 2^{5-2} example are shown in Table 2. So, if an analysis of the results found out that A was an active effect, it is technically only true that $A + BCD + BE + ACDE$ is active. In most cases, it will be safe to assume that this can be shortened to $A + BE$, or possibly even A , as we discuss below.

In general, a 2^{k-p} design contains p generators. We call each term in the defining relation a *word*, and in general a 2^{k-p} design contains 2^p words (including I) in the defining relation.

The *length* of a word is defined to be the number of letters it contains, so $ABCE$ would have length 4. The design resolution (see **Factorial Designs, Resolution of**) is defined to be the length of the shortest word (excluding I) in the defining relation. For example, the resolution of the 2^{5-2} design is 3. This is often written as III and, for the example, the design is sometimes denoted by 2^{5-2}_{III} . The practical implication of this is that in a resolution III design some main effects are confounded with one

or more two-factor interactions; in a resolution IV design some two-factor interactions are confounded with each other, but not with main effects; and neither two-factor interactions nor main effects are confounded with each other in a resolution V design. A finer distinction, known as *aberration* (see **Minimum Aberration**) is usually made among designs of equal resolution.

The 2^{k-p} designs are examples of orthogonal arrays (see **Orthogonal Arrays**). They are also examples of *geometric designs*, which are designs in which each effect is either totally confounded with or orthogonal to every other effect. For example, in the 2^{4-1} design, AB is totally confounded with CD , but is orthogonal to all other effects.

Design Construction

Consider a fixed value of the number of factors k and fractionation element p (or, equivalently, run size n). Principles such as resolution, aberration, or number of clear effects [1] can be used to compare 2^{k-p} designs to find which are optimal. However, the number of such potential designs grows rapidly with k except for special values of p , such as $p = 1$. Because theoretical results were not available aside from these special cases, optimum designs had traditionally been derived using algorithms, for example, Franklin and Bailey [2], and these in turn have been used to create tables of optimal designs. Examples may be found in Box *et al.* [3], Wu and Hamada [4], and Lorenzen and Anderson [5]. These references include designs for k as large as 5–16 and n up to 64. These or similar designs are also available in many statistical software packages.

More theoretical results have since been obtained that find optimum designs for certain (k, p) combinations without the use of algorithms. See, for example, Chen and Wu [6] and Chen [7], who found minimum aberration (MA) designs for $p = 3, 4, 5$, and Tang and Wu [8], Chen and Hedayat [9], and Butler [10], who found MA designs for $n = 2^{k-p}$ runs and $5n/16 \leq k < n$ factors.

In practice, the following points may serve as useful guides to the resolution of designs:

1. If $k \leq n/2$, a fractional factorial design of resolution IV or higher can be constructed. If $k > n/2$, the design will be resolution III.

Table 2 Confounding in the 2^{5-2} example

$I = ABCD = ABE = CDE$
$A = BCD = BE = ACDE$
$B = ACD = AE = BCDE$
$C = ABD = ABCE = DE$
$AB = CD = E = ABCDE$
$AC = BD = BCE = ADE$
$BC = AD = ACE = BDE$
$ABC = D = CE = ABDE$

4 Fractional Factorial Designs

2. Any design of resolution III may be folded over (see **Foldover Designs**) to form a design of resolution IV.
3. A 2^{k-1} design of resolution k always exists, and can be constructed by aliasing the k th factor with the interaction involving all of the other $k - 1$ factors.
4. For any design of resolution R , any subset of $R - 1$ factors or fewer form a full factorial design, possibly replicated. For example, the 2^{5-1} design with $I = ABCDE$ has resolution V, so any subset of one to four factors forms a full factorial design. This is another example of the projectivity of these designs.

Finney [11] was the first to develop a general theory of fractional factorial design construction.

Uses, Advantages, and Disadvantages

Two-level fractional factorial designs have been used extensively and productively in industry for over half a century. One use has been as the first experiment in sequential experimentation (see **Sequential Experimentation**). Here, the experimenter has many factors of potential importance but likely only a few that will actually turn out to be important. For this reason, these designs are also known as *screening designs* (see **Screening Designs**). Such designs may need to accommodate a large number of factors, so these must often be run as resolution III designs. Because follow-up designs are expected and these follow-up designs can be used to resolve uncertainties, an initial design of resolution III is acceptable. See [3], for example, for the uses of such designs.

These designs can also be effective in one-shot experiments – see Ledolter [12], for example, for a detailed case study. These designs also form the basis for experimentation both in robust designs (see **Robust Design**) and in tolerance designs (see **Tolerance Design**).

Most areas in which process complexity precludes theoretical prediction, in which more than a few factors need to be studied, and in which data may be collected are amenable to these designs. These features make these designs appealing across a broad range of fields. For example, Snelick *et al.* [13] study software code that “was described as a ‘complex benchmark’ that would be almost impossible to tune”. Using a 2_{IV}^{31-25} design, the authors found

important bottlenecks in the code and subsequently analyzed and reduced them. They point out the ability of this method to “eliminate (screen) uninteresting factors in linear time”. As another example, these designs are often used in *conjoint analysis*. This is a technique used in marketing to examine different combinations of attributes, often during the design of a new product, by presenting them to subjects. See, for example, Louviere [14].

Two advantages of these designs have already been noted: a *large number of factors* may be studied in a *relatively small number of runs*. In addition, because these designs are orthogonal, it can be shown that each factor’s effects are estimated with maximum precision, that is, the same precision that would have been obtained if only that factor was under study (e.g., only factor A in Table 1). These designs are also balanced, just as the full factorial designs from which they were derived – for example, factor A is run at both of its settings an equal number of times. Well-chosen designs usually also have the property that the maximum number of potentially active effects are unconfounded with each other.

Suppose that each factor has levels that may be varied in a continuum between the low and high settings, and that the response (aside from random error) is expected to be a smooth function of the factors’ coded levels. Then, locally, the function may be approximated by a first-order Taylor series expansion. If so, the main effects of the design are estimates of the coefficients of the first-order partial derivative terms (after division by 2, to adjust for the coded range from -1 to $+1$), based on the secant method of approximating derivatives, so the equation developed from these terms provides this first-order model. In addition, testing for active two-factor interactions can be used as a test of lack of fit (see **Lack of Fit**) to see if the first-order model is reasonable.

Other advantages of these designs stem from their close association with factorial designs. For example, large regions of design space are explored and **outliers** have a relatively small effect on the results and are also relatively easy to detect. To ensure that all of these advantages exist, these designs should be run in conjunction with other fundamental statistical design principles, such as randomization, **blocking** (which will be discussed in a later section), and other more general design principles, such as careful selection of factors and their levels.

The key disadvantage of these designs arises when the results of the analysis are unclear due to confounding. To return to the 2^{5-2} example, suppose only the effects associated with $A + BE$ and $D + CE$ were found to be active (where effects of three-factor interactions and higher were omitted from the list). Most experimenters, following the principle of simplicity (sometimes called *Occam's razor*) would declare that A and D were active. The reason is that it would be very unusual for, say, BE to be active even though neither B nor E were active. However, suppose instead that only the effects associated with $A + BE$, $B + AE$, and $E + AB + CD$ were found to be active. Then the principle of simplicity fails to point to one model: the “ A, B, E ” scenario is simple, but so are those of “ A, B, AB ”, “ A, E, AE ”, and “ B, E, BE ”.

The experimenter's prior knowledge can often reduce the likelihood of this problem. In this example, the experimenter should assign the factor least likely to be active (and so, reasonably, least likely to interact with other factors) to the letter E – this can be seen from considering various scenarios and looking only at the main effect and two-factor interactions in Table 2. More generally, this strategy is to (a) select a design with good properties for the particular values of k and p for the experiment and (b) assign the actual factors to the symbols $A, B, \dots$ on the basis of prior knowledge to minimize confounding of effects most likely to be active. Such a strategy is another advantage of fractional factorial designs – the prior knowledge of the experimenter can be used directly in the design of the experiment.

If the data have already been collected and this problem exists, another way to see which factors are active is to collect an additional set of data to eliminate the confounding. This is often done by running a foldover design (see **Foldover Designs**). A more sophisticated approach developed by Meyer *et al.* [15] may also be used, by adding those runs that allow maximum discrimination among a set of plausible models.

If confounding exists and no more data can be collected, it may still be possible to obtain a good solution. In this confounding example, if the objective is to maximize the response and each of the three effects associated with $A + BE$, $B + AE$, and $E + AB + CD$ is positive, then setting A, B , and E at their high levels from the experiment is a good strategy regardless of which of the four scenarios

above is correct. In other experiments, a “pick the winner” strategy may work – simply run at those conditions that produced the best result.

Another disadvantage sometimes seen in these designs is that it may be difficult to distinguish the active effects from the intrinsic variability in the data. However, the ability to make this distinction depends on the total number of runs made, not on the extent of confounding, so this is not a disadvantage of fractional factorial designs *per se*. A reasonable rule of thumb to overcome this shortcoming is to use at least 16 runs in an experiment and especially avoid experiments with 8 or fewer runs [16]. In our example, this would mean that the experimenter should replace the 2^{5-2} design with a 2^{5-1} design. This has the additional advantage of increasing the resolution from III to V. (This is also usually preferred to running a 2^{5-2} design followed by a foldover design, which also requires 16 runs but is only resolution IV.)

Most of our discussion assumes that the design is for a physical (real-life) experiment, that is, an experiment whose results include random variation. By contrast, designs for **computer experiments** that produce deterministic results usually employ other design strategies, such as Latin hypercube designs (see **Latin Hypercube Designs**), to allow smooth nonlinear functions to be fit in the design region. However, if a large number of factors are being studied, and most are expected to be monotonic in the response, then 2^{k-p} designs may still be useful.

Example

Our example comes from an experiment that was described in Snee *et al.* [17]. (The design and analysis have been slightly modified here for simplicity.) Viscosity measurements made in an analytical laboratory appeared to be quite variable, and it was not clear how much of this variation was due to the product itself and how much was due to the variation in the **measurement system**. A classical way to study variation in measurement systems is by a gauge repeatability and reproducibility (R&R) experiment (see **Gauge Repeatability and Reproducibility (R&R) Studies**). There, an attempt is typically made to vary systematically both product samples and those who make the measurements, while trying to hold other

6 Fractional Factorial Designs

conditions constant. Here a more active approach was taken – conditions in the analytical laboratory were intentionally varied over ranges typically used in the laboratory. This use of experimentation is known as a *ruggedness test* [18, 19].

The factors, settings, and results for this experiment are listed in Table 3. Factors *A* and *B* involved methods that were both used in the laboratory as part of an accepted protocol and factors *C*, *D*, and *E* were run over the ranges that had historically been used in the laboratory. For a 16-run design, these five factors could be run in a resolution V design. The chemists in the lab were not as interested in running factors *F* and *G* because they believed these would not be important. However, they agreed to it when they were told these could be included without the need for additional runs (although the resolution of this seven-factor design is IV). The generators for this 2^{7-3} design were chosen to be *BCDE*, *ACDF*, and *ABCG*, resulting in the defining relation $I = BCDE = ACDF = ABEF = ABCG = ADEG = BDFG = CEF G$.

In these 16 runs, factors *A*, *B*, *C*, and *D* form a set of basic factors and the data in Table 3 are listed in the “standard order” for these factors. The 15 effects from these basic factors were calculated and appear in Table 4, with aliasing up through two-factor interactions. These 15 effects were plotted on a half-normal plot (see **Half-Normal Plot**) and Lenth’s

method (see **Lenth’s Method for the Analysis of Unreplicated Experiments**) was used to add decision lines to this plot for $\alpha = 0.05$ ME (margin of error) and SME (simultaneous margin of error) values – see Figure 2.

From this figure, there is good evidence that the main effects of factors *D* (mix time), *C* (mix speed) and *F* (spindle) are active, as well as the effect of $AD + CF + EG$. Because the main effects of both *C* and *F* are large and those of *A*, *E*, and *G* are not,

Table 4 Effects calculated for the viscosity ruggedness test

Effect name	Effect
<i>A</i>	3.5
<i>B</i>	−136.5
<i>C</i>	463.5
<i>D</i>	−300.5
<i>E</i>	113.5
<i>F</i>	−656.5
<i>G</i>	19.5
<i>AB</i> + <i>CG</i> + <i>EF</i>	−28.5
<i>AC</i> + <i>BG</i> + <i>DF</i>	55.5
<i>AG</i> + <i>BC</i> + <i>DE</i>	−72.5
<i>AD</i> + <i>CF</i> + <i>EG</i>	−248.5
<i>BD</i> + <i>CE</i> + <i>FG</i>	65.5
<i>AF</i> + <i>BE</i> + <i>CD</i>	−8.5
<i>AE</i> + <i>BF</i> + <i>DG</i>	−38.5
<i>ABD</i> + other 3 fi’s	37.5

Figure 2 Half-normal plot and Lenth's method applied to the effects from the viscosity ruggedness test

it is reasonable to suspect that the interaction effect is primarily or totally due to the CF interaction. (In fact additional runs were later made to deconfound these terms, and these verified that CF was the active interaction.)

So, aside from making a decision about the $AD + CF + EG$ interaction, the analysis of this design is equivalent to that for a full factorial 2^k design. This is generally true. Also, because fractional factorial designs can accommodate a large number of factors, the study was able to include the spindle factor, and this proved to have the largest effect on the results.

Extensions

The 2^{k-p} designs are the simplest examples of fractional factorial designs. They may be extended in many ways. We consider extensions to blocked designs, **split-plot** designs, three-level and higher-level symmetric designs, nongeometric designs, **supersaturated** designs, and mixed-level designs.

Blocked Designs

Blocking (see **Blocking**) can be a very useful technique to reduce, as well as to identify, experimental error, the sources of which can be hypothesized by

the experimenter. In a full factorial design, simple blocking may be used. For example, in a 2^3 design with factors A , B , and C , suppose that variation is suspected among batches of some raw material, that 8 runs may be made per batch, and that 16 runs are planned to obtain enough precision to detect interesting effects. Then a natural design would be to run all 2^3 combinations on each of the two batches. Here, the units run in each batch are called a *block*, so this design has two blocks, each of size 8.

Now suppose we instead want to study five factors in 16 runs, but still use two blocks of size 8. We could run the same 2^{5-2} fraction in each of the two blocks, but it is more advantageous to run different fractions in each block to reduce the confounding.

One way to approach this problem is to consider a 16-run design in five factors, and then add a so-called blocking factor. Here, we could consider the generator $E = ABCD$ for the 2^{5-1} design and then define a blocking factor $b_1 = AB$. The 2^{5-1} design is then split into two blocks on the basis of the value of b_1 . The resulting defining relation is $I = ABCDE = ABb_1 = CDEb_1$. If we consider that at most main effects and two-factor interactions are a concern, then we can eliminate $ABCDE$ from consideration. Furthermore, in industrial experiments it is customary to assume that the blocking factor(s) will not interact with the treatment factors. If so, under this additional assumption we may write $I = ABb_1$. This shows that all main effects and two-factor interactions are clear of each other and of the blocking factor, except for AB , which is confounded with b_1 .

Suppose we instead need to consider splitting up this 2^{5-1} design into four blocks, each of size 4. A good design to use here is $E = ABCD$, $b_1 = AB$, $b_2 = AC$. This generates four blocks based on the four combinations of (b_1, b_2) , $\{(-1, -1), (+1, -1), (-1, +1), (+1, +1)\}$. These are associated with the 3 degrees of freedom (df) (see **Degrees of Freedom**) due to b_1 , b_2 , and b_1b_2 . The last term, sometimes called a *generalized interaction*, has the same status as b_1 and b_2 . The defining relation is $I = ABCDE = ABb_1 = CDEb_1 = ACb_2 = BDEb_2 = BCb_1b_2 = ADEb_1b_2$.

In this example, we began with $I = ABCDE$, the best design without blocking, and achieved from it the optimal blocked design. This is not always the case. For example, if we need to run a 2^{5-1} design in eight blocks instead of four, we need to start with

a four-letter generator such as $ABCD$ to create the optimal blocked design.

Sometimes trade-offs need to be considered for these designs. For example, say we want to run a 2^{5-1} design in two blocks. We could choose our earlier design, whose defining relation is $I = ABCDE = ABb_1 = CDEb_1$. The weakness of this design is that the block is confounded with the AB interaction. If we instead choose a design whose defining relation is $I = ABCE = ABD b_1 = CDE b_1$, then the blocking factor is no longer confounded with a two-factor interaction; however three pairs of two-factor interactions ($AB + CE$, $AC + BE$, and $AE + BC$) are confounded instead. A listing of two-level blocked designs that also includes this trade-off information may be found in Sun *et al.* [20].

Split-Plot Designs

In many industrial experiments, some factors have levels that are more difficult to change than others. For example, consider an experiment with eight factors, and suppose that four of them, $A - D$, have levels that are relatively difficult to change. Say they can only be run at one setting each day. Suppose the other four factors, $P - S$, are easier to adjust and can be run at two settings each day. Say we can make two runs per day and can run the experiment for 8 days. The resulting design is an example of a split-plot design (see **Split-Plot Designs**). Here, $A - D$ are called *main-plot factors* and each set of two runs per day is called a *main plot*. The factors $P - S$ are called *split-plot factors* and an individual run is called a *split plot*.

For this problem a 2^{8-4} design is suggested, but can such a design be constructed such that the levels of $A - D$ can be run in pairs, as required? This additional restriction makes the construction of these designs more difficult. In this case, such a design is possible, using basic factors A, B, C , and P , and generators $D = ABC$, $Q = BCP$, $R = ACP$, and $S = ABP$. (In fact, this design has minimum aberration (see **Minimum Aberration**) among all 2^{8-4} designs.) See Huang *et al.* [21] and Bingham and Sitter [22] for examples and listings of some designs and Bingham and Sitter [23] for more theoretical details.

More restrictive situations are also common. For example, perhaps some factors will only be varied once every 2 days, some once each day, others twice

each day, and others every hour. The resulting split-split-split-plot design may be more difficult, or even impossible, to construct. Extensive listings for such designs are not available.

Higher-Level Symmetric Designs

Although two-level designs have traditionally been the most widely used in industrial applications, higher-level fractional factorial designs are also used. These include designs in which each factor is run at the same number of levels – such designs are called *symmetric designs*. We illustrate some basic ideas with geometric, three-level, fractional factorial designs.

The confounding that was used in two-level designs, for example, $D = ABC$, cannot be directly extended to higher-level designs. In this two-level example, both the D main effect and the ABC interaction had 1 df, and this made it possible to consider confounding the two effects. However, in a three-level design, the D main effect has 2 df, but the ABC interaction has 8 df, so “ $D = ABC$ ” no longer makes sense. It is possible, however, to confound D with what is called a *2 df piece* of the ABC interaction. In fact, the ABC interaction has four such pieces, and an additional factor could be confounded with each piece. Details on how to create such designs may be found in, for example [4, 5].

Not surprisingly, the resulting confounding in 3^{k-p} designs is much more complex than in 2^{k-p} designs. So-called interaction graphs provide a useful way to examine the implications of these interactions. Sun and Wu [24] provide listings of good 3^{k-p} designs, including interaction graphs.

Higher-level designs for s^{k-p} are available when s is prime or a power of a prime. Such designs are not used often in industrial applications. The arrays used in Latin squares (see **Latin Squares and Related Experimental Designs**) and Greco-Latin squares are equivalent to s^{3-1} and s^{4-2} designs, respectively. In the original development of those designs, only one of the factors was a treatment factor, the remainder being blocking factors. However, these designs may also be used to define fractional factorials, in which all of the factors can be treatment factors.

These symmetric designs are examples of orthogonal arrays (see **Orthogonal Arrays**) of strength 2 or greater (as long as main effects are not confounded

with each other – such confounding is almost always avoided in good experiments).

Nongeometric Symmetric Designs

The 2^{k-p} and 3^{k-p} designs are geometric designs, but designs with more complex aliasing are sometimes used. The most common of these are the Plackett–Burman designs (see **Plackett–Burman Designs**). These two-level designs exist for all $N \leq 200$ whenever N modulo 4 = 0, and the designs have complex aliasing unless N is a power of 2 (in which case the design is a 2^{k-p} design). For an example of this complex aliasing, consider an experiment in which five factors, labeled $A - E$, are studied using the levels based on the first five columns of a 20-run Plackett–Burman design that is generated as shown in **Plackett–Burman Designs**. An example of the resulting aliasing is that the effect associated with column **A** is an estimate of $A + (-BC - BD - BE + CD - CE + DE)/5$. Thus the main effect of A is neither fully orthogonal to nor fully aliased with these interactions. This type of aliasing distinguishes nongeometric designs from geometric designs.

These designs are most widely used when $N = 12, 20, 24, 28$, because they fill in the gaps between the 8-, 16-, and 32-run 2^{k-p} designs.

Supersaturated Designs

For two-level designs in which N is an appropriate value, such as those noted in the previous subsection, up to $N - 1$ factors may be studied in an orthogonal design. Occasionally, consideration may be given to studying more than $N - 1$ factors in N runs, and the resulting fractional factorial design is called *supersaturated* (see **Supersaturated Designs**). These may also be constructed for designs other than two-level designs.

Mixed-Level Designs

Designs in which factors are not all run at the same number of levels are called *mixed-level designs*. Constructing fractions of such designs that have desirable properties, such as orthogonality, is often more complex than for symmetric designs.

The most common of these designs are the resolution III designs, known as *main effect plans* (see

Main Effect Designs) or *orthogonal main effect designs*, also called OMEDs. For example, it is possible to construct an OMED with 7 factors at three levels and 16 factors at two levels in 32 runs, and notation such as “ $3^7 2^{16} // 32$ ” may be used to denote this design. As another example, consider the 2^{5-1} design in four blocks that we had constructed earlier. If we replace the four-level blocking factor with a four-level treatment factor, we have created a $2^5 4^1 // 16$ design.

A listing of such designs for factors having 2–6 levels and 50 runs or fewer is available in [5]. More general orthogonal designs, known as *orthogonal arrays* (see **Orthogonal Arrays**), can also be constructed. Also, see Chen *et al.* [25] for a listing of mixed-level designs at two and three levels.

Closing Remarks

The construction of fractional factorial designs has been, and continues to be, extensively studied. A large number of good designs are available from the references cited, and are also available from numerous statistical software programs and electronic resources including the National Institute for Standards and Technology [26]. Many statistical software programs can create other designs from user requirements, using algorithms based on design-construction rules or optimal-design theory (see **Optimal Design**).

Analysis methods for designs include subjective graphical methods, Lenth’s method (for orthogonal designs), or more sophisticated techniques (see **Lenth’s Method for the Analysis of Unreplicated Experiments** for some examples).

Gauge Repeatability and Reproducibility (R&R) Studies

Introduction and Some Qualitative Matters

A given measurement device (henceforth called a *gauge*) is often used by more than one individual (henceforth called *operators*) to make routine measurements of some important feature of production outcomes (henceforth called *parts*). In such cases it is important to quantify measurement consistency (or lack thereof), both for a fixed operator on a fixed part, and between operators on a fixed part. The first kind of consistency or variation is commonly called the *repeatability* component and the second is termed the *reproducibility* component. Where remeasurement is possible, it is traditional to try to assess these two components of measurement variation by having each of J operators measure each of I parts m times apiece, producing a balanced $I \times J$ **factorial** dataset with responses

$$y_{ijk} = \text{the } k\text{th measurement of part } i \text{ by operator } j \quad (1)$$

$i = 1, 2, \dots, I$; $j = 1, 2, \dots, J$; and $k = 1, 2, \dots, m$. (It is obvious that where remeasurement is not possible, e.g. because measurement is destructive, there can be no direct assessment of measurement precisions unclouded by part-to-part differences. A discussion of what can be done indirectly on the basis of different sets of assumptions in the destructive testing context is provided in **Gauge Repeatability and Reproducibility (R&R) Studies, Destructive Testing.**)

It should go without saying that in the collection of gauge R&R data, some scheme of rotation should be employed so that all m observations in a part-by-operator cell are not collected one after another, creating psychological pressure on the operator to get unnaturally consistent results. Complete **randomization** of the order of making IJm measurements may not be feasible, but operators making m “repeats” one after another will produce repeatability variation that is really too small, and quite

likely reproducibility variation that is really too large.

Further, what is under investigation in an R&R study is essentially *variances* and functions thereof. For example, reproducibility variation might be conceptualized as a between-operator variance. Sound statistical intuition should be that the effective **estimation** of variances requires relatively large “sample sizes.” While in a typical gauge R&R study, there are IJm measurements, there are only J operators, and standard industry **data collection** forms and spread sheets for calculation are typically set up for J on the order of 2–5! This feature of common practice is thus in clear contradiction to well-recognized statistical realities.

It is standard to talk about gauge R&R as if measurement precision were a property of only the gauge and how it is used. This is, of course, not really the case. The same gauge used to measure different features of the same part can yield different precisions of measurement. The same gauge used to measure the same feature of otherwise “identical” parts made of two different materials can yield different precisions of measurement. (Consider, for example, using a caliper to measure “the diameter” of 3 cm nominally circular cylinders made of precision machined stainless steel and then some made of wood.) This has the implication that the extension of gauge R&R results from one specific context to another can only be on the basis of expert judgment (that the two contexts are similar enough that results from one predict those from the other).

Strictly interpreted, “R&R” has nothing to do with part-to-part variation (except as the reality above impacts observed variability in measurement). And standard analyses of R&R data do not really require the presence of more than 1 part in the study nor produce inferences about part-to-part variation. Nevertheless, typical data collection forms (and spread sheets for calculation) are typically set up for I on the order of 10. To the extent that anyone would actually look carefully at results for different parts and consider whether the models and analyses used with gauge R&R data are appropriate in light of part-to-part comparisons, this is perhaps not a bad thing. But in practice, it seems to create the illusion of having “lots of information” because IJm is large, while it is basically really *only* J that governs how much can be learned about the fundamental issue of reproducibility.

Standard Models and Analyses

Standard analyses for gauge R&R data are based on the two-way random-effects model

$$y_{ijk} = \mu + \alpha_i + \beta_j + \alpha\beta_{ij} + \epsilon_{ijk} \quad (2)$$

where all of the random effects $\alpha_i, \beta_j, \alpha\beta_{ij}, \epsilon_{ijk}$ are independent, the α_i are $N(0, \sigma_\alpha^2)$, the β_j are $N(0, \sigma_\beta^2)$, the $\alpha\beta_{ij}$ are $N(0, \sigma_{\alpha\beta}^2)$, and the ϵ_{ijk} are $N(0, \sigma^2)$. Notice that in a case where $I = 1$ (there is only one part involved in the R&R study) this is

$$y_{1jk} = \mu + \alpha_1 + \beta_j + \alpha\beta_{1j} + \epsilon_{1jk} \quad (3)$$

and with $\gamma_j = \beta_j + \alpha\beta_{1j}$ this is

$$y_{1jk} = \mu + \alpha_1 + \gamma_j + \epsilon_{1jk} \quad (4)$$

For $\sigma_\gamma^2 = \sigma_\beta^2 + \sigma_{\alpha\beta}^2$, the γ_j are $N(0, \sigma_\gamma^2)$ and this is a variant of the one-way random-effects model where it is obviously impossible to disentangle the parameters μ and σ_α^2 that are not of primary concern in this context. Rather, it is the two variances

$$\sigma_{\text{reproducibility}}^2 \equiv \sigma_\gamma^2 = \sigma_\beta^2 + \sigma_{\alpha\beta}^2 \quad (5)$$

and

$$\sigma_{\text{repeatability}}^2 \equiv \sigma^2 \quad (6)$$

that are of primary interest. The first of these can be thought of as representing a variance of operator-specific measurement biases.

The best available technologies for inference in the two-way random-effects model (2) or in the case of a single part, the usual one-way random-effects model, are

- so-called “reml” estimation as implemented, for example, in the R statistical package and described in Pinheiro and Bates [1]
- Bayes analyses using “flat prior distributions” as can, for example, be implemented using the WinBUGS program (see <http://www.mrc-bsu.cam.ac.uk/bugs/welcome.shtml>).

The most commonly used technologies for inference from gauge R&R datasets are

- range-based point estimates as described in the Automotive Industry Action Group [2]

- ANOVA-based inference, with confidence statements based on Satterthwaite approximations and various improvements thereof represented by Burdick and Graybill [3] and subsequent related work (*see Gauge Repeatability and Reproducibility (R&R) Studies, Confidence Intervals for*).

Of the commonly used methods, the ANOVA methods are expected to be superior to the range-based ones on the basis of both efficiency of point estimation and the fact that they provide confidence statements about $\sigma_{\text{reproducibility}}^2$, $\sigma_{\text{repeatability}}^2$, and $\sigma_{\text{R\&R}}^2 \equiv \sigma_{\text{repeatability}}^2 + \sigma_{\text{reproducibility}}^2$. Of the best existing technologies, Bayes analyses have the potential advantage of being both very simple to implement and also providing obvious ways to find credible limits based on posterior distributions not only for $\sigma_{\text{reproducibility}}^2$, $\sigma_{\text{repeatability}}^2$, and $\sigma_{\text{R\&R}}^2$, but also for other parametric functions as well like, e.g., the ratios $(\sigma_{\text{reproducibility}}^2 / \sigma_{\text{R\&R}}^2)$ and $(\sigma_{\text{repeatability}}^2 / \sigma_{\text{R\&R}}^2)$.

Figures of Merit for R&R Study Designs

Now consider the question of “How good is a particular choice of I, J , and m for an R&R study?” Strictly speaking, any quantitative figure of merit to be associated with a given choice (henceforth, a “design”) for a gauge R&R study should be matched to the method of estimation employed in analyzing the results. But in the interest of providing simple explicit formulas, we are here going to consider what might be done for ANOVA-based estimation.

Let us begin with an R&R study using a single part, i.e. the $I = 1$ instance of the balanced R&R data structure. It is completely standard that with the obvious meaning of treatment mean square ($MSTr$) and error mean square (MSE), for a balanced dataset $MSTr$ and MSE are multiples of independent χ^2 random variables with respective **degrees of freedom** $J - 1$ and $J(m - 1)$ and

$$EMSTr = m\sigma_\gamma^2 + \sigma^2 \text{ and } EMSE = \sigma^2 \quad (7)$$

and thus variances

$$\text{Var}MSTr = \frac{2(m\sigma_\gamma^2 + \sigma^2)^2}{(J - 1)} \text{ and}$$

$$\text{Var}MSE = \frac{2\sigma^4}{J(m-1)} \quad (8)$$

So with

$$\hat{\sigma}_{\text{reproducibility}}^2 = \frac{1}{m} (MSTr - MSE) \quad (9)$$

and

$$\hat{\sigma}_{\text{repeatability}}^2 = MSE \quad (10)$$

the vector $\begin{pmatrix} \hat{\sigma}_{\text{repeatability}}^2 \\ \hat{\sigma}_{\text{reproducibility}}^2 \end{pmatrix}$ has **covariance** matrix

$$\begin{pmatrix} \frac{2\sigma^4}{J(m-1)} & -\frac{2\sigma^4}{Jm(m-1)} \\ -\frac{2\sigma^4}{Jm(m-1)} & \frac{2(m\sigma_\gamma^2 + \sigma^2)^2}{m^2(J-1)} + \frac{2\sigma^4}{Jm^2(m-1)} \end{pmatrix} \quad (11)$$

And with

$$\hat{\sigma}_{\text{R\&R}}^2 = \frac{1}{m} MSTr + \frac{(m-1)}{m} MSE \quad (12)$$

one has

$$\begin{aligned} E\hat{\sigma}_{\text{R\&R}}^2 &= \sigma_{\text{R\&R}}^2 \text{ and} \\ \text{Var}\hat{\sigma}_{\text{R\&R}}^2 &= \frac{(m-1)2\sigma^4}{Jm^2} + \frac{2(m\sigma_\gamma^2 + \sigma^2)^2}{m^2(J-1)} \end{aligned} \quad (13)$$

It is obvious then that precision of estimation of $\sigma_{\text{reproducibility}}^2$ and $\sigma_{\text{repeatability}}^2$ and $\sigma_{\text{R\&R}}^2$ depend upon the values of the two variance components. But simple formulas like equations (11) and (13) allow one to input planning values for σ_γ^2 and σ^2 and trial values for J and m and get some idea of the quality of information about important parametric functions that could be achieved. (Further, Taylor series/propagation of error approximations applied to nonlinear functions of $(\hat{\sigma}_{\text{repeatability}}^2, \hat{\sigma}_{\text{reproducibility}}^2)$ can be used to get some rough idea of what one can expect to learn about a corresponding nonlinear function of $(\sigma^2, \sigma_\gamma^2)$ from a particular choice of design.) Vardeman and VanValkenburg [4] took the above kind of approach to the full-blown design question for an $I \times J \times m$ gauge R&R study based on means and variances of ANOVA mean squares. They found, e.g., that the determinant of the covariance matrix for linear

combinations of mean squares that are unbiased for $(\sigma^2, \sigma_\gamma^2)'$ can be written in fairly explicit terms as

$$4\sigma^8 \frac{(1+mr)^2 + m^2(I-1)t^2}{I^2 J m^2 (J-1)(m-1)}$$

for $r = \sigma_\gamma^2/\sigma^2$ and $t = \sigma_\beta^2/\sigma^2$. One might take this as a single figure of merit for a particular choice of I, J , and m where only $\sigma_{\text{repeatability}}^2$ and $\sigma_{\text{reproducibility}}^2$ are to be estimated. Note that this figure of merit does not depend upon σ_α^2 . (Recall that the variance components were defined in the section titled "Standard Models and Analyses.") Not too surprisingly, for a given set of planning values for variance components (equivalently values for r and t) and given total number of measurements IJm , this criterion causes one to prefer choices with $I = 1$ if only the narrow issue of optimizing it is considered. More details on this kind of analysis can be found in the Vardeman and VanValkenburg paper.

Conclusion

Most gauge R&R studies have the fairly simple structure of a replicated full factorial design. Nevertheless, we have here identified some ways in which they are often poorly suited to their supposed purpose, and provided some ways of evaluating whether a proposed design is likely to provide information adequate to really identify repeatability and reproducibility components of measurement variance.

STEPHEN B. VARDEMAN

Half-Normal Plot

A half-normal plot is a graphical display of effect estimates (contrasts) from a factorial experiment (see **Factorial Experiments**) to discern active contributors from inert ones. It was introduced in Daniel [1] and is a popular data analysis tool for factorial experiments involving factors at two levels, especially without replication. Many have developed alternatives to Daniel's approach including Box and Meyer [2] and Lenth [3] (see **Lenth's Method for the Analysis of Unreplicated Experiments**). See Hamada and Balakrishnan [4] for a detailed overview and comparison of this method with many others.

The basic idea is to rank order the absolute value of the effect estimates and to display them on a special probability graph. If the underlying distribution of the data is normal, the effect estimates also follow a **normal distribution**. The absolute values of these effect estimates are nonnegative, and when the true effects are zero, their corresponding distribution is a half-normal, which resembles the right half of a bell-shaped curve. When the estimates of these null effects are sorted and plotted against **quantiles** of a half-normal distribution, they should follow a straight line extending from the origin. When there are nonzero effects in the experiment, their absolute values should deviate from the straight-line pattern formed by the estimates of the null effects. Any effect that deviates from this line would be considered a significant contributor. This approach is particularly useful when there are no replicates in the experiment and no estimate of error variance to gauge the magnitude of these effects. Even though the method is designed to compare effects from the popular class of two-level factorial experiments (see **Factorial Experiments**; **Fractional Factorial Designs**; **Main Effect Designs**; **Screening Designs**; and Box *et al.* [5]), it can be adapted to compare standardized effects from experiments with more than two levels.

Define an effect estimate as the difference between the average response at the high setting and the average response at the low setting for that effect, which is also twice the regression coefficient obtained by fitting a linear regression model with the two levels of each factor coded to -1 and 1 (see **Main Effects**). Consider an experiment with $N = 2^{k-p}$ runs, where k is the number of two-level factors

and p is the fraction order. For $k = 4$ and $p = 0$, one would have a 16-run full factorial experiment (see **Factorial Experiments**). For $k = 5$ and $p = 1$, one would have a one-half fraction of a 32-run experiment, which could study five factors with 16 runs (see **Fractional Factorial Designs**). The effect estimates are computed from differences of averages of $N/2$ runs of the experiment.

Table 1 summarizes a four factor experiment from an integrated circuit manufacturing process, taken from Table 3-1 of [6]. Assume that a linear model is appropriate for this experiment.

$$Y_{ijklm} = \mu + A_i + B_j + C_k + D_l + AB_{ij} + AC_{ik} + AD_{il} + BC_{jk} + BD_{jl} + CD_{kl} + ABC_{ijk} + ABD_{ijl} + ACD_{ikl} + BCD_{jkl} + ABCD_{ijkl} + \varepsilon_{ijklm} \quad (1)$$

Y_{ijklm} represents the response and μ represents the overall average response. ε represents an independent random error term, which has a zero mean and variance σ^2 . For this full factorial experiment, all the effects can be estimated. The terms in equation (1) excluding μ and ε represent these 15 effects, and can be expressed as twice the regression coefficients if the low and high levels are coded to -1 and 1 . Since there is no replication in the above experiment, there is no estimate for residual variance and no

2 Half-Normal Plot

analysis of variance (*see Analysis of Variance*) to assess the significance of these effects.

Under the effect sparsity principle, namely, only a small portion of effects are likely to be active in an experiment, so one would compare the effect estimates in equation (1) against each other and identify the extremely large ones as likely contributors to the experiment.

Table 2 lists the effect estimates of the experiment in Table 1, and Figure 1 plots their absolute values against the corresponding half-normal quantiles. From the above example, the main effect (*see Main Effects*) estimate for factor A is -0.0775 because the average response at the “1” setting of A is 14.1225 and the average response at the “ -1 ” setting of A is 14.2. Their difference is -0.0775 . If levels of factor A are coded as -1 and 1, a first-order regression model would yield a slope of -0.03875 for this factor. The effect estimates for interaction terms (*see Interactions*) can be found by multiplying the columns of the corresponding factors and then taking the difference of the average response associated with the “1” setting and the average response associated with the “ -1 ” setting. For example, the effect estimate for the AB interaction is 0.0075 because the

Table 2 Effect estimates from the four-factor experiment shown in Table 1

Effect label	Estimate
A	-0.0775
B	0.1725
C	-0.0775
D	-0.4900
AB	0.0075
AC	-0.0925
AD	0.0500
BC	0.0575
BD	0.0300
CD	0.3450
ABC	0.0975
ABD	-0.0250
ACD	0.0300
BCD	-0.1100
ABCD	-0.0200

average response at the “1” setting of AB is 14.165 and the average response at the “ -1 ” setting of AB is 14.1575.

Take the absolute value of these effect estimates and assign half-normal scores associated with

Figure 1 Half-normal plot for the example in Table 1. The main effects B and D and the interaction effect CD stand out as active contributors in this experiment

them. Let $\hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_M$ be the effect estimates, and $|\hat{\beta}|_{(1)} < |\hat{\beta}|_{(2)} < \dots < |\hat{\beta}|_{(M)}$ be the ordered absolute effect estimates. $M = N - 1$ when the experiment involves only two-level factors. For the i th ordered absolute effect estimate $|\hat{\beta}|_{(i)}$, compute its half-normal score by $\Phi^{-1}(0.5 + 0.5(i - 0.5)/M)$. Then plot $|\hat{\beta}|_{(i)}$ on the vertical axis *versus* its half-normal score on the horizontal axis. $\Phi^{-1}(\cdot)$ is the inverse of the standard normal distribution function, namely, $\Phi(x) = \int_{-\infty}^x 1/\sqrt{2\pi} \exp(-z^2/2) dz$.

The use of the half-normal plot is preferred over a regular normal plot, because the visual ability to identify large contributors in a regular normal plot is obscured when these contributors are spread out in both the positive and the negative directions. They are more visible when plotted in their absolute values on a half-normal plot.

This analysis technique can also be used in fractional factorial designs (see **Fractional Factorial Designs**). The basic approach is the same as before except that the confounding structure of the experiment is labeled, so that the correct active effects are identified. For example, consider Exercise 9 in Chapter 6 of Box *et al.* [5], where an experiment with 16 runs was conducted to study the impact of five welding parameters on the heat input (y). Tables 3 and 4 display the factor description, the raw data, and the design. This is a one-half fraction of a 32-run experiment. Only 15 out of 31 effects can be estimated.

This design is a resolution- V design (see **Factorial Designs, Resolution of**) where the main effects (see **Main Effects**) are confounded with (inseparable from) the fourth-order interaction effects (see **Aliasing in Fractional Designs**). Using the defining relationship of this design, one would find the confounding pattern of all the effects. For example, the interaction effect (see **Interactions**) AB is inseparable from CDE . Hence, they are aliases of each other. Table 5 lists the effect estimates and

Table 3 Factor description for the welding example

5	−1	1	1	1	−1	2485
9	1	1	1	1	1	2450

their corresponding aliases (see **Aliasing in Fractional Designs**). Figure 2 exhibits these effects in a half-normal plot. On the basis of experience, many have argued that lower-order effects (main and second-order effects) are more likely to dominate in an experiment than higher-order effects (fourth- and fifth-order effects). Therefore, the effects listed in the left column of Table 5 are the likely effects when they appear to deviate from the line in the half-normal plot.

In a 2^{k-p} fractional factorial experiment (see **Fractional Factorial Designs**), the half-normal plot still consists of $N - 1$ effect estimates but some of them are confounded with other effects. It is the user's task to ensure the interpretation of active contributors with their associated aliases.

The $N - 1$ effect estimates in the two-level factorial experiments are orthogonal contrasts. To extend this approach to factorial experiments involving three- or higher-level factors, one would need to construct orthogonal contrasts and standardize them so that they have a common variance before plotting. Because there are a number of ways to construct orthogonal contrasts for three- or higher-level factors, there are multiple half-normal plots for the same experiment. The experimenter should decide which set of orthogonal contrasts is relevant to the factors.

The half-normal plot is a popular tool to identify “active” effects in a two-level factorial or fractional factorial experiment because of its ease of use, simplicity, and graphical nature. However,

4 Half-Normal Plot

one weakness of this approach is its subjectivity in identifying active contributors. Even though Daniel [1] proposed a way to quantify significance of effects, most practitioners ignore this aspect of the method. Many have proposed ways to augment this ocular approach with more objective criteria to determine “significance”. For example, Zahn [7]

provided “guardrails” for the half-normal plots. See Hamada and Balakrishnan [4] for a list of these alternatives, technical comparisons, and recommendations. Other nontraditional fractionated designs also favor the half-normal plot as a data analysis tool. These include Plackett–Burman designs (*see Plackett–Burman Designs*) and orthogonal arrays (*see Orthogonal Arrays*).

The half-normal plot provides a means to identify large contributors in an experiment. However, additional work such as model selection, diagnostic, and confirmation study should follow to complete the analysis of the experiment.

WINSON TAAM

Block Designs, Incomplete

Introduction

One of the Fisherian principles of good experimentation (*see* **Factorial Experiments**) is the stratification of the available experimental material into homogeneous blocks (*see* **Blocking**), so that treatments may be compared within blocks. An experiment in which v treatments are to be compared using b blocks of size k_j , $j = 1, \dots, b$, is called a *blocked experiment*, and if $k_j < v$ for at least one block, the experiment is known as an *incomplete block experiment*. The resulting allocation of treatments to the blocks is called an *incomplete block design* (IBD). For example, in an experiment to compare the tastes of six antibiotic syrups for children, it was considered inadvisable to subject any child to more than three of the antibiotics. Here $v = 6$ and the children formed the blocks with block size $k_j = 3$ for all j . Suppose that the six treatments are represented by the symbols 1, 2, $\dots$, 6. The problem is to allocate sets of three treatments to a group of b children so that all treatments could be compared. All treatment comparisons were of equal importance, so that a design formed from all possible combinations of the six treatment symbols taken three at a time would suffice. A total of ${}^6C_3 = 20$ children would be required to form the IBD shown in Table 1.

This is an example of an *unreduced balanced incomplete block design* (UBIBD); *balanced* because all treatments are equally represented and *unreduced* because all possible sets of three treatments are used. For larger v , the number of blocks needed to produce a UBIBD can become unmanageably large, this prompts one to look for designs that use fewer blocks but maintain balance or partial balance if full balance is not possible. An example of a reduced balanced incomplete block design (BIBD) for six treatments requiring only 10 blocks of three treatments per block is shown in Table 2.

Table 2 Reduced balanced incomplete block design in 10 blocks of three treatments per block

2	2	3	3	4	3	3	4	5	5
5	6	4	6	5	4	5	6	6	6

Early Development and General Properties of Balanced Incomplete Block Designs

Yates [1, 2] first described the use of IBDs in large-scale agricultural trials to compare crop varieties, but since then an extensive literature has been produced on different construction methods and analyses for IBDs. Bose [3, 4] and Fisher [5] considered the structure and construction of BIBDs. Partially balanced incomplete block designs (PBIBD) were introduced by Bose and Nair [6]. Further extensions of the BIBDs were made by Youden [7], who introduced BIBDs for eliminating heterogeneity in two directions, extending the Latin square concept (*see* **Latin Squares and Related Experimental Designs**) to Youden “squares”.

Although for given v and k , a BIBD always exists (the unreduced design for example), there are constraints placed on the number of blocks and treatment replications for the existence of reduced BIBDs. In a BIBD, each treatment is replicated r times and each block size is k . If λ is the number of times each pair of treatments occurs together in the same block, then the five parameters, v , b , k , r , and λ (all integers), must satisfy the conditions:

$$vr = bk = n \text{ where } n \text{ is the number of experimental units} \quad (1)$$

$$\text{and } \lambda(v - 1) = r(k - 1) \quad (2)$$

Shrikhande [8] showed that these are necessary but not sufficient conditions for a reduced BIBD to exist.

Table 1 An unreduced balanced incomplete block design in 20 blocks of three treatments per block

2	2	2	2	3	3	3	4	4	5	3	3	3	4	4	5	4	4	5	5
3	4	5	6	4	5	6	5	6	6	4	5	6	5	6	6	5	6	6	6

2 Block Designs, Incomplete

For example, there is no BIBD with parameters $v = 21, b = 28, r = 8, k = 6$, and $\lambda = 2$, even though equations (1) and (2) are satisfied. For certain parameter combinations satisfying these equations, it is possible to use complete sets of orthogonal Latin squares (see **Latin Squares and Related Experimental Designs**) to produce BIBDs. For example, suppose that $v = t^2$ and $k = t$, where t is a prime (or power of a prime); then the complete set of $t - 1$ orthogonal Latin squares may be used to produce a BIBD with $b = t(t + 1)$, $r = t + 1$, and $\lambda = 1$. The t^2 treatments are first arranged sequentially in a $t \times t$ square. The first t blocks of the BIBD are the rows of the square, the second t blocks are the columns of the square; then for each of the $t - 1$ orthogonal Latin squares, a set of t blocks is produced corresponding to the treatments associated with the same symbol in the Latin square. For example, for $t = 3$, the $v = 9$ treatment symbols are laid out in the 3×3 square as below, together with the two orthogonal Latin squares given by Roman and Greek letters,

1	2	3	<i>a</i>	<i>b</i>	<i>c</i>	α	β	γ
4	5	6	<i>b</i>	<i>c</i>	<i>a</i>	γ	α	β
7	8	9	<i>c</i>	<i>a</i>	<i>b</i>	β	γ	α

Table 3 shows the 12 blocks, in four sets of three blocks, for the corresponding BIBD produced using this method.

This construction method necessarily produces $t + 1$ sets of t blocks where each set contains all t^2 treatments. Such BIBDs are called *resolvable designs*. For every BIBD there is a second BIBD, with the same number of treatments and blocks, formed from the treatments not in the blocks of the first BIBD. Such a BIBD is known as a *complementary BIBD*. For the BIBDs formed from the orthogonal Latin squares described above, the complementary BIBD has parameters $v = t^2, k = t(t - 1), b = t(t + 1), r = t^2 - 1$, and $\lambda = t^2 - t - 1$. Table 4 shows

Table 3 BIBD produced from a complete set of orthogonal 3×3 Latin squares ($v = 9, k = 3, b = 12, r = 4, \lambda = 1$)

9	9	6	9	9	8	7	7	9	8	8	7

the complementary BIBD for the design given in Table 3.

Further BIBDs with $v = t^2 + t + 1$ and $k = t + 1$ may be produced from these orthogonal Latin square BIBDs by adding one of the additional $t + 1$ treatment symbols to each set of t blocks and including an additional block consisting of all $t + 1$ additional treatments. In this way, BIBDs with parameters $v = t^2 + t + 1, k = t + 1, b = t^2 + t + 1, r = t + 1$, and $\lambda = 1$ are derived. In each case, a complementary BIBD with parameters $v = t^2 + t + 1, k = t^2, b = t^2 + t + 1, r = t^2$, and $\lambda = t(t - 1)$ may also be constructed. Tables 5 and 6 give the extension of the BIBD in Table 3 and its complementary design respectively. Tables of BIBDs, produced this way and using other methods of construction, are available in Fisher and Yates Statistical Tables [9]. An easy to use catalog of designs, including BIBDs, is available at www.designtheory.org. See Khare and Federer [10] for an alternative method of constructing resolvable BIBDs.

Analysis of a General Incomplete Block Experiment

The usual method of analyzing an incomplete block experiment is to use the intrablock analysis based

Table 5 BIBD produced by extending Table 3 ($v = 13, k = 4, b = 13, r = 4, \lambda = 1$)

Block number												
1	2	3	4	5	6	7	8	9	10	11	12	13
1	4	7	1	2	3	1	2	3	1	2	3	10
2	5	8	4	5	6	6	4	5	5	6	4	11
3	6	9	7	8	9	8	9	7	9	7	8	12
10	10	10	11	11	11	12	12	12	13	13	13	13

on comparisons of treatments made within the same block, with block differences eliminated. For a general IBD, suppose that n_{ij} is the number of times treatment i , for $i = 1, 2, \dots, v$, is applied in the j th block, $j = 1, 2, \dots, b$, and that the corresponding response is y_{ijm} , for $m = 1, 2, \dots, n_{ij}$. Suppose that the model for y_{ijm} is the additive linear form

$$y_{ijm} = \mu + \tau_i + \beta_j + \varepsilon_{ijm} \quad (3)$$

where μ is a general mean level, τ_i is the effect of the i th treatment, β_j is the effect of the j th block, and ε_{ijm} is an error term with mean zero and variance σ^2 independent of any other error term. This model is overparameterized so that the parameters are not estimable without some restrictions being imposed to make them well defined. However, the objective here is to estimate contrasts in the treatment parameters, $\tau_i - \tau_j$, together with their appropriate standard errors, so that the treatments may be compared. We shall see that such contrasts may be estimable even though the individual parameters are not uniquely estimable. Equation (3) can be expressed in matrix notation as

$$\mathbf{y} = \mathbf{W}\boldsymbol{\alpha} + \boldsymbol{\varepsilon} \quad (4)$$

where $\mathbf{y}$ and $\boldsymbol{\varepsilon}$ are $n \times 1$ vectors of responses and error terms respectively, $\boldsymbol{\alpha}$ is a $p \times 1$ vector of parameters (with $p = 1 + v + b$), and $\mathbf{W}$ is the $n \times p$ design matrix of 1's and 0's identifying the treatments and blocks. The conditions on $\boldsymbol{\varepsilon}$ are that $E(\boldsymbol{\varepsilon}) = \mathbf{0}$ and $V(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$, where $\mathbf{I}$ is the identity matrix. The columns of the $\mathbf{W}$ matrix can be partitioned into three submatrices corresponding to the parameter μ , the treatment effect parameters τ_i , for $i = 1, 2, \dots, v$, and the block effect parameters

β_j , for $j = 1, 2, \dots, b$. The matrix $\mathbf{W}$ and the vector $\boldsymbol{\alpha}$ can be partitioned as $\mathbf{W} = (\mathbf{1}|\mathbf{X}|\mathbf{Z})$ and $\boldsymbol{\alpha} = (\mu|\boldsymbol{\tau}'|\boldsymbol{\beta}')$, where $\mathbf{1}$ is a column of all 1's and $\mathbf{X}$ and $\mathbf{Z}$ are the $(n \times v)$ and $(n \times b)$ design matrices for treatments and blocks respectively. An alternative form for the model (4) is

$$\mathbf{y} = \mathbf{1}\mu + \mathbf{X}\boldsymbol{\tau} + \mathbf{Z}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (5)$$

The matrix $\mathbf{X}$ is such that $\mathbf{X}'\mathbf{1} = \mathbf{r}$, where $\mathbf{r} = (r_1, r_2, \dots, r_v)'$ is the vector of replications of each treatment and $\mathbf{X}'\mathbf{X} = \mathbf{r}^\delta$ where $\mathbf{r}^\delta$ is a diagonal matrix whose diagonal elements are those of the vector $\mathbf{r}$. Similarly, if $\mathbf{k}$ is a vector whose j th element is k_j , the number of units in the j th block, then $\mathbf{Z}'\mathbf{1} = \mathbf{k}$ and $\mathbf{Z}'\mathbf{Z} = \mathbf{k}^\delta$. Now, $\mathbf{X}'\mathbf{Z} = \mathbf{N}$, a $(v \times b)$ matrix, called the *incidence matrix* of the design, with ij th element equal to n_{ij} . If $\mathbf{T}$ and $\mathbf{B}$ are vectors of treatment and block totals respectively and if G is the overall total of the responses, then $\mathbf{X}'\mathbf{y} = \mathbf{T}$, $\mathbf{Z}'\mathbf{y} = \mathbf{B}$, and $\mathbf{1}'\mathbf{y} = G$. The least-squares estimator of the parameter vector $\boldsymbol{\alpha}$ is obtained by minimizing the sum of squared errors with respect to $\boldsymbol{\alpha}$. The normal equations are $\mathbf{W}'\mathbf{W}\hat{\boldsymbol{\alpha}} = \mathbf{W}'\mathbf{y}$. Partitioning $\mathbf{W}$ and $\boldsymbol{\alpha}$ as described above gives

$$n\hat{\mu} + \mathbf{r}'\hat{\boldsymbol{\tau}} + \mathbf{k}'\hat{\boldsymbol{\beta}} = G \quad (6)$$

$$\mathbf{r}\hat{\mu} + \mathbf{r}^\delta\hat{\boldsymbol{\tau}} + \mathbf{N}\hat{\boldsymbol{\beta}} = \mathbf{T} \quad (7)$$

$$\mathbf{k}\hat{\mu} + \mathbf{N}'\hat{\boldsymbol{\tau}} + \mathbf{k}^\delta\hat{\boldsymbol{\beta}} = \mathbf{B} \quad (8)$$

These equations do not have a unique solution because the matrix $\mathbf{W}'\mathbf{W}$ has rank $\leq v + b - 1$. The problem of finding a solution to equations (6–8) can be simplified by eliminating $\hat{\mu}$ and $\hat{\boldsymbol{\beta}}$. The resulting reduced normal equations for the intrablock analysis are

$$\mathbf{A}\hat{\boldsymbol{\tau}} = \mathbf{Q} \quad (9)$$

where $\mathbf{Q} = \mathbf{T} - \mathbf{N}\mathbf{k}^{-\delta}\mathbf{B}$ is the vector of treatment totals adjusted for blocks, and $\mathbf{A} = \mathbf{r}^\delta - \mathbf{N}\mathbf{k}^{-\delta}\mathbf{N}'$ is the intrablock treatment information matrix of the design. Equation (9) has a solution $\hat{\boldsymbol{\tau}} = \boldsymbol{\Omega}\mathbf{Q}$ for any generalized inverse $\boldsymbol{\Omega}$ of $\mathbf{A}$, i.e. for any matrix $\boldsymbol{\Omega}$ such that $\mathbf{A}\boldsymbol{\Omega}\mathbf{A} = \mathbf{A}$. If the overall mean μ is estimated using the sample mean $\bar{y}$, the block parameters $\hat{\boldsymbol{\beta}}$ are $\hat{\boldsymbol{\beta}} = \mathbf{k}^{-\delta}\mathbf{B} - \mathbf{k}^{-\delta}\mathbf{N}'\hat{\boldsymbol{\tau}} - 1\bar{y}$. Different generalized inverses, $\boldsymbol{\Omega}$, give different estimates, $\hat{\boldsymbol{\tau}}$, of the specific treatment parameters, but, provided the design is connected, treatment differences are

Table 6 Complementary BIBD produced from the BIBD in Table 5 ($v = 13, k = 9, b = 13, r = 9, \lambda = 6$)

4 Block Designs, Incomplete

uniquely estimable. A block design is *connected* if it is possible to compare any two treatments directly within a block, or indirectly across several blocks; otherwise it is disconnected. For example, the two-block design in four treatments, two treatments per block {1, 2} and {3, 4}, is disconnected. The condition for connectedness is $\text{rank}(\mathbf{A}) = v - 1$. Provided the design is connected, a set of s linear combinations of the treatment effects can be written as $\mathbf{C}\boldsymbol{\tau}$, where $\mathbf{C}$ is an $s \times v$ contrast matrix with each row holding the coefficients, which sum to zero, of a treatment comparison. In this case, $E(\mathbf{C}\hat{\boldsymbol{\tau}}) = \mathbf{C}\boldsymbol{\tau}$ and $V(\mathbf{C}\hat{\boldsymbol{\tau}}) = \mathbf{C}\boldsymbol{\Omega}\mathbf{C}'\sigma^2$.

Intrablock Analysis of Variance for Connected Designs

The further assumption that the error terms $\boldsymbol{\varepsilon}$ are multivariate normally distributed is required when carrying out significance tests or setting **confidence intervals**. The total **sum of squares**, $\mathbf{y}'\mathbf{y}$, for the general linear model in equation (5) can be partitioned into three components

$$\mathbf{y}'\mathbf{y} = \mathbf{B}'\mathbf{k}^{-\delta}\mathbf{B} + \hat{\boldsymbol{\tau}}'\mathbf{Q} + (\mathbf{y} - \mathbf{W}\hat{\boldsymbol{\alpha}})'(\mathbf{y} - \mathbf{W}\hat{\boldsymbol{\alpha}}) \quad (10)$$

where $\hat{\boldsymbol{\alpha}}$ is any solution of the normal equations. This decomposition is invariant to the choice of generalized inverse $\boldsymbol{\Omega}$. The first component is the block sum of squares, the second term is the extra sum of squares due to treatments adjusting for blocks, and the last term is the residual sum of squares. The analysis of variance (*see Analysis of Variance*) shown in Table 7 may be used to test the overall null hypothesis $H_0: \tau_1 = \tau_2 = \dots = \tau_v$, using $F = \hat{\boldsymbol{\tau}}'\mathbf{Q}/(v-1)/s^2$ as an $F_{v-1, n-b-v+1}$ variable, where s^2 is the residual mean square.

A specific set of contrasts $\mathbf{C}\boldsymbol{\tau} = \mathbf{0}$ may be tested using the sum of squares $(\mathbf{C}\hat{\boldsymbol{\tau}})'(\mathbf{C}\boldsymbol{\Omega}\mathbf{C}')^{-1}(\mathbf{C}\hat{\boldsymbol{\tau}})$ with **degrees of freedom** equal to the rank of $\mathbf{C}$.

Analysis of a Balanced Incomplete Block Design

This general analysis simplifies if the design is a BIBD, since in this case, $\mathbf{r} = r\mathbf{1}_v$, $\mathbf{k} = k\mathbf{1}_b$, $\mathbf{r}^\delta = r\mathbf{I}_v$, and $\mathbf{k}^\delta = k\mathbf{I}_b$, where $\mathbf{1}_a$ is a vector of a 1s and $\mathbf{I}_a$ is the $a \times a$ identity matrix. In this case, $\mathbf{A} = \mathbf{r}^\delta - \mathbf{N}\mathbf{k}^{-\delta}\mathbf{N}'$ becomes $\mathbf{A} = r\mathbf{I}_v - \frac{1}{k}\mathbf{N}\mathbf{N}'$, where $\mathbf{N}\mathbf{N}'$ is the *concurrency matrix* of the design with

$$\mathbf{N}\mathbf{N}' = \begin{pmatrix} r & \lambda & \dots & \lambda \\ \lambda & r & \dots & \lambda \\ \vdots & \vdots & \ddots & \vdots \\ \lambda & \lambda & \dots & r \end{pmatrix} = (r - \lambda)\mathbf{I}_v + \lambda\mathbf{J}_v \quad (11)$$

where $\mathbf{J}_v$ is a $v \times v$ matrix of 1's.

Therefore $\mathbf{A} = \frac{\lambda}{k}[\mathbf{v}\mathbf{I}_v - \mathbf{J}_v]$, with g inverse $\boldsymbol{\Omega} = \frac{k}{\lambda v}\mathbf{I}_v$, so that a solution of the normal equations is

$$\hat{\boldsymbol{\tau}} = \boldsymbol{\Omega}\mathbf{Q} = \frac{k}{\lambda v}\mathbf{Q} = \frac{k}{\lambda v}\left(\mathbf{T} - \frac{1}{k}\mathbf{N}\mathbf{B}\right) \quad (12)$$

For any contrast matrix, $\mathbf{C}$, $\mathbf{C}\hat{\boldsymbol{\tau}}$ is the least-squares estimator of $\mathbf{C}\boldsymbol{\tau}$ with

$$V(\mathbf{C}\hat{\boldsymbol{\tau}}) = \mathbf{C}\boldsymbol{\Omega}\mathbf{C}'\sigma^2 = \frac{k}{\lambda v}\mathbf{C}\mathbf{C}'\sigma^2 \quad (13)$$

The difference between two treatment effects τ_{i_1} and τ_{i_2} ($i_1 \neq i_2$) is estimated by $\mathbf{l}'\hat{\boldsymbol{\tau}}$ with $\mathbf{l}' = (0, \dots, 1, \dots, -1, \dots, 0)$, that is $\hat{\tau}_{i_1} - \hat{\tau}_{i_2}$ with $\text{var}(\hat{\tau}_{i_1} - \hat{\tau}_{i_2}) = \frac{k}{\lambda v}\mathbf{l}'\mathbf{l}\sigma^2 = \frac{2k}{\lambda v}\sigma^2$. This is the same regardless of which two treatments are being compared, a consequence of the balance of the design. For a complete block design with r replicates of each treatment, the variance of the estimated treatment difference is $\text{var}(\hat{\tau}_{i_1} - \hat{\tau}_{i_2}) = 2\sigma^2/r$, giving the efficiency of a BIBD as $\lambda v/(rk)$.

An Example of the Analysis of an Incomplete Block Design

The reduced BIBD with $v = 6$ treatments in $b = 10$ blocks of $k = 3$ treatments per block, shown in

Table 7 Intrablock analysis of variance for the general incomplete block experiment

Source of variation	Degrees of freedom	Sum of squares	Mean squares
Treatments eliminating blocks	$v - 1$	$\hat{\boldsymbol{\tau}}'\mathbf{Q}$	$\hat{\boldsymbol{\tau}}'\mathbf{Q}/(v - 1)$
Blocks ignoring treatments	$b - 1$	$\mathbf{B}'\mathbf{k}^{-\delta}\mathbf{B} - G^2/n$	—
Residual	$n - b - v + 1$	by subtraction	s^2
Total (after fitting mean)	$n - 1$	$\mathbf{y}'\mathbf{y} - G^2/n$	—

Table 8 BIB design, shown in bold, and taste data for the comparison of six antibiotic formulations with each subject receiving three treatments

Subject (block)	1	2	3	4	5	6	7	8	9	10
	1	5	1	3	1	2	1	5	1	3
	2	5	2	3	4	4	5	5	3	3
	3	5	4	5	1	6	5	6	4	6
Total	15	10	7	15	12	5	8	9	10	9

Table 8, was used as the basic design in a larger comparative study of antibiotic formulations for children, described by Prescott *et al.* [11]. Table 8 also shows, for the first 10 children, the responses relating to taste, as indexed by the selection of an appropriate facial expression ranging from a sad face (1) to a smiley face (5). These data are used here as a simple illustration of the calculations involved in an analysis of a BIBD, but for the full data set nonparametric ranking methods were employed.

For this design, $r = 5$ and $\lambda = 2$, so that the incidence matrix, $\mathbf{NN}'$, the intrablock treatment information matrix, $\mathbf{A}$, and a possible generalized inverse, $\mathbf{\Omega}$, are given by $\mathbf{NN}' = (r - \lambda)\mathbf{I}_v + \lambda\mathbf{J}_v = 3\mathbf{I}_6 + 2\mathbf{J}_6$, $\mathbf{A} = \frac{\lambda}{k}[\nu\mathbf{I}_v - \mathbf{J}_v] = \frac{2}{3}[6\mathbf{I}_6 - \mathbf{J}_6]$, and $\mathbf{\Omega} = \frac{k}{\lambda\nu}\mathbf{I}_v = \frac{1}{4}\mathbf{I}_6$, so that $\hat{\tau} = \mathbf{\Omega Q} = \frac{k}{\lambda\nu}\mathbf{Q} = \frac{1}{4}(\mathbf{T} - \frac{1}{3}\mathbf{NB})$. Since the treatment and block totals are $\mathbf{T}' = (18, 13, 19, 23, 10, 17)$ and $\mathbf{B}' = (15, 10, 7, 15, 12, 5, 8, 9, 10, 9)$ respectively, this particular solution for $\hat{\tau}$ is given by $\hat{\tau}' = \frac{1}{12}(-5, -8, 11, 17, -16, 1)$. The unadjusted and adjusted treatment means are shown in Table 9. Table 10 gives the analysis of variance from which

it is evident that there are significant differences among the treatments. The variance of any pairwise treatment difference is $\text{var}(\hat{\tau}_{i_1} - \hat{\tau}_{i_2}) = \frac{2k}{\lambda\nu}\sigma^2 = \sigma^2/2$, which is estimated using $s^2/2 = 0.956/2 = 0.478$ with 15 degrees of freedom. Any pair of treatment estimates which differ by more than $0.478^{1/2} \times 2.13 = 1.47$ are significantly different. This suggests that antibiotic formulations 3 and 4 are significantly different from formulations 2 and 5 but not significantly different from formulations 1 and 6.

Further Developments and Related Topics

Kiefer [12] and John and Mitchell [13] discuss optimality (see **Optimal Design**) of IBDs when v divides n , based on minimization of the E-criterion that examines the largest variance over all (normalized) treatment contrasts. The former proposed families of criteria and provided some rigorous proofs, while the latter produced examples of designs satisfying the optimality conjecture. Further details are given in John and Williams [14]. Computer software packages are now available for the construction of optimal or near-optimal block designs, e.g. Nguyen [15].

It is possible to extend the analysis of BIBDs to include recovery of the interblock information on the treatments by considering the block effects to be random effects. Details of this extended analysis and methods of combining the intra- and interblock information are given in John [16, pp. 233–248], see also Federer [17].

Table 9 Unadjusted and adjusted treatment means

Treatment	1	2	3	4	5	6
Means (unadjusted)	3.6	2.6	3.8	4.6	2.0	3.4
Means (adjusted)	−0.417	−0.667	0.917	1.417	−1.333	0.0833

Table 10 Intrablock analysis of variance for the antibiotics example

Source of variation	Degrees of freedom	Sum of squares	Mean squares	F value	P value
Treatments eliminating blocks	5	21.00	4.200	4.40	0.012
Blocks ignoring treatments	9	31.33	3.481	3.64	0.013
Residual	15	14.33	0.956	—	—
Total (after fitting mean)	29	66.67	—	—	—

PHILIP PRESCOTT

Interactions

Interaction

Interaction refers to the joint nature of the effect of two or more explanatory variables on a response variable. When the interaction involves two factors, it is referred to as a *two-way interaction*, three factors suggest a three-way interaction, and so forth. The existence of interaction effects means that the effect of one factor on the outcome depends on the levels of another factor. For example, if factors *A* and *B* are said to exhibit interaction, the effect of *A* on the response variable cannot be completely expressed unless the level of *B* is first specified. Interactions are common in many applications of experimental practice. For a discussion of the importance of interactions in experimental practice, Box [1] provides a useful illustration of interactions in both agricultural and engineering contexts. Cox [2] provides a comprehensive review and formal treatment of the definition, detection, and interpretation of interactions. Here we restrict our attention to interactions between two treatment variables. For further reading on interactions among various subsets of random (nonspecific) factors and intrinsic factors, see Cox [2].

Methodology

For concreteness, suppose that a **factorial** experiment yields a response Y_{ijk} measured on experimental unit k at level $i = 1, \dots, I$ of factor *A* and at level $j = 1, \dots, J$ of factor *B*. Further, suppose that n_{ij} experimental units are measured with *A* at level i and *B* at level j (so that $k = 1, \dots, n_{ij}$). One possible representation of a model that relates the response variable to the two explanatory variables is

$$Y_{ijk} = \mu_{ij} + \epsilon_{ijk} \quad (1)$$

where the μ_{ij} values are the *cell means* and the error terms, ϵ_{ijk} are independent and identically distributed (i.i.d.) $N(0, \sigma^2)$. This representation is convenient and main effects (*see Main Effects*) and interactions for the parameters can be expressed as contrasts of

the cell means. For example, suppose factor *A* has $I = 2$ levels and factor *B* has $J = 2$ levels. Then the cell means can be represented in a two-way layout, as in Table 1.

To define interactions in terms of cell means, we first begin with the definition of simple effects. Simple effects are defined as the contrasts between different levels of one factor at a single level of a second factor. If a factor only has two levels, this contrast becomes the difference between the two cell means. In the case above, an example of a simple effect is

$$(\mu_{11} - \mu_{12})$$

Interactions, then, are differences between simple effects. In the simple setup above, the interaction between *A* and *B* is defined as

$$(\mu_{11} - \mu_{12}) - (\mu_{21} - \mu_{22})$$

In more complex situations (situations with multiple levels on factor *A* or factor *B* or additional factors) the interaction can still be expressed as a difference of simple effects, but there are many different ways to express the simple effects as contrasts.

A second model for relating the response Y_{ijk} to factors *A* and *B* is the *effects model*, which can be expressed in the interaction form as

$$Y_{ijk} = \mu + \alpha_i + \beta_j + \gamma_{ij} + \epsilon_{ijk} \quad (2)$$

where γ_{ij} describes the interaction effect of level i of factor *A* and level j of factor *B* on the response Y_{ijk} . Implicit in the interaction model is the notion that the effect of *A* on the response variable is differentially expressed depending on the levels of factor *B*. The model as stated here is not identifiable, however, the following constraints are often used as a means of

Table 1 Two-way layout of cell means

		Factor A	
		1	2
Factor B	1	μ_{11}	μ_{12}
	2	μ_{21}	μ_{22}

2 Interactions

making the model identifiable,

$$\sum_{i=1}^I \alpha_i = 0 \quad (3)$$

$$\sum_{j=1}^J \beta_j = 0 \quad (4)$$

$$\sum_{i=1}^I \gamma_{ij}, \text{ for all } j \text{ and} \quad (5)$$

$$\sum_{j=1}^J \gamma_{ij}, \text{ for all } i \quad (6)$$

For a discussion on the identifiability of this model and the restrictions required to make this model identifiable, *see Analysis of Variance*. The effects model is the basis for most statistical software packages, and is therefore the most common choice for practitioners.

Designs for Detection of Interactions

Factorial designs (*see Factorial Experiments*) are commonly used as a design technique that allows assessment of the presence or absence of interaction

effects. The full factorial design allows for **estimation** of main effects and interactions between factors under consideration. For experimental problems in which the number of factor levels or the number of factors is high, a full factorial design is often infeasible due to the large number of experimental runs required.

In cases when full factorial designs are infeasible, fractional factorial designs (*see Fractional Factorial Designs*) may still provide insight into some interaction effects. In particular, resolution-IV and higher-resolution (*see Factorial Designs, Resolution of*) designs often have the ability to clearly estimate a subset of all possible two-factor interactions. If the design cannot distinguish between certain interactions, the interactions are said to be aliased. For a complete discussion on the aliasing of effects and the relation of aliasing to fractional factorial designs and interactions, *see Aliasing in Fractional Designs*.

Detection of Interaction Effects

An effective tool used to determine the presence or absence of a two-factor interaction is a plot of the estimated cell means, $\hat{\mu}_{ij}$, *versus* the levels of factor A. Further, the cell means associated with the same level of factor B are connected by lines of the

Figure 1 Two notional interaction plots. The solid lines indicate the first level of Factor B, the dotted lines indicate the second level of factor B. (a) Lines which are parallel, suggesting the absence of an interaction between factors A and B. (b) Lines which are not parallel, suggesting the presence of an interaction between factors A and B

Figure 2 Interaction plot for the tread wear experiment. Depicted are the cell means for each treatment combination. The solid line represents axle configuration 1 and the dotted line represents axle configuration 2

same type. This organization of cell means by factor combinations is often referred to as an *interaction plot*. Figure 1 is a notional depiction of an interaction plot where factor *A* has three levels and factor *B* has two levels. Two possible scenarios are depicted, one in which *A* and *B* exhibit interaction, and one in which *A* and *B* exhibit no interaction. In each plot, the different line types indicate the different levels of factor *B*. Figure 1(a) reveals that the two different lines are not parallel, suggesting that factor *A* interacts with factor *B* in determining the effect on the response. More concisely stated, Figure 1 indicates an interaction between factors *A* and *B*. Figure 1(b) shows the two lines for factor *B* to be parallel, which suggests that the effect of factor *A* is consistent, regardless of the level of factor *B* (and *vice versa*).

The interaction graph provides a powerful and valuable tool for addressing the presence or absence of interaction. However, many scientists and engineers wish to validate the visual determination with a more formal assessment of the presence or absence of interactions. Using analysis of variance (ANOVA) (see **Analysis of Variance**), *F*-tests can be constructed to test the presence of an interaction between two factors. The *F*-test makes it possible to check whether an observed interaction is so large that it could not have occurred by chance. If the *F*-test is not statistically significant, there is not strong evidence against the assumption that the factors do affect the

response independently. This requires a reinterpretation of the main effects. Reinterpretation of the main effects tests is often cumbersome and many authors suggest that the main effects have no real meaning [3]. Other authors [4, 5] have suggested that interactions can be framed in terms of conditional main effects, which is the interpretation required when a significant interaction effect exists.

Example

A commercial truck tire manufacturer proposes an experimental design approach to the evaluation of tire wear for four different tire constructions. In addition, the tire manufacturer is concerned about the effect of axle configurations on tire wear. In order to address the interaction between tire construction (*A*,

Table 2 Data from the two-factor tread wear experiment

A	B	Replicate 1	Replicate 2	Replicate 3	Replicate 4

^(b)SS: sum of squares.

^(c)MS: mean square.

with four levels) and axle configuration (B , with two levels), a full factorial design was constructed with four randomly selected tires of each tire construction assigned to each of the two axle configurations. The tread depth as measured in centimeters for each of the four tires was recorded after 25 000 mi. The data are shown in Table 2.

A graphical display of the cell means is depicted in Figure 2. The horizontal axis contains the different tire construction types (1, 2, 3, or 4). The vertical axis is the tread depth measurement in centimeters. The cell means for each of the two different axle configurations are connected by lines, where the solid line represents the cell means for axle configuration 1 and the broken line represents the cell means for axle configuration 2. Because these two lines are not parallel, suspicion of a potential interaction might be raised. In particular, it appears that while the measured tread is deeper (larger values of tread depth) for tire construction 2 at axle configuration 2, the opposite effect is observed for tire construction 3. That is, for tire construction 3, axle configuration 1 appears to provide a deeper tread measurement than axle configuration 2. It appears that tire construction and axle configuration interact with each other.

To formalize this visual inspection of the interaction effect, the ANOVA table for this experiment is shown in Table 3. The p value for the interaction effect is small (0.0032), confirming the visual inspection of Figure 2. While the **main effect** p value is also small, caution should be taken when interpreting a main effect in the presence of a significant interaction. However, further analysis of Figure 2 reveals that this small p value associated with the main effect of tire construction is most likely driven by the significantly different tread depths for tire construction 2.

Higher-Order Interactions

In an investigational study, it is often of interest to examine the effect of three or more factors on a response variable. This may be particularly true in an early phase of experimentation where there is an understanding of the many factors which *potentially* relate to a response variable, but the exact nature of those relationships is unclear. In this situation, higher-order interactions (three factor, four factor, etc.) may exist. These higher-order interactions are fairly simple to detect using an F -test. However, while these effects may exist, in practice it is often difficult to provide a tractable interpretation of interaction effects above three-way interactions. Visualization of four-factor and higher-order interactions using interaction plots is infeasible. In general, interactions between more than three factors are difficult to interpret and the associated **degrees of freedom** from such effects may be more effectively used to more precisely estimate the error. This pooling of higher-order interactions is discussed extensively in Hocking [6], Dean and Voss [7], and Box *et al.* [8].

Latin Hypercube Designs

Introduction

Latin hypercubes were introduced by McKay *et al.* [1] in 1979, and provide useful designs for **computer experiments** and numerical integration. Evans and Swartz [2] offer a detailed discussion on various numerical integration methods. Santner *et al.* [3] provide a careful account of the design and analysis of computer experiments (*see Computer Experiments*). A recent book on computer experiments is that of Fang *et al.* [4].

Latin hypercubes are easy to generate, making them especially attractive for experts who do not specialize in design theory. Latin hypercubes achieve the maximum uniformity in each of the univariate margins of the design region, thus allowing the experimenter to use models that are capable of capturing the complex dependence of the response variable on the input variables. Another reason that contributes to the popularity of Latin hypercubes is that they have no repeated runs. Repeated runs do not bring about extra information in computer experiments as running a deterministic computer code twice yields identical output.

Latin hypercubes are a very large class of designs. A design may not perform well in terms of other criteria such as those of orthogonality or space filling, simply because it is a Latin hypercube. A design that spreads its points evenly in the design region is referred to as a *space-filling design*; such a design allows information to be collected from all portions of the design region. Many authors have contributed to this area of selecting good Latin hypercubes, and some of the ideas will be briefly described in this article.

Definition and Basic Properties

An $n \times m$ matrix $D = (d_{ij})$ is called a *Latin hypercube* of n runs for m factors if each column of D is a permutation of $1, \dots, n$. What makes Latin hypercubes distinctly different from other designs is that every factor in a Latin hypercube has the same number of levels as the run size. Because of this property, Latin hypercubes might be totally impractical for a field or laboratory experiment but are easy to

implement in the context of a computer experiment or a numerical integration.

Let $y = f(x_1, \dots, x_m)$ be a real-valued function with m variables. For convenience, all the variables are now coded to the unit interval $[0, 1]$, and therefore the design region is $[0, 1]^m$. The design region will be allowed to take a more general form when we discuss Latin hypercube sampling later in this section. The function represents the deterministic computer model in the case of computer experiments or the integrand in the case of numerical integration. There are two natural ways of generating a *Latin hypercube design* based on a given Latin hypercube. The first is through

$$x_{ij} = \frac{(d_{ij} - 0.5)}{n} \quad (1)$$

with the n points given by $(x_{i1}, \dots, x_{im})$ with $i = 1, \dots, n$. The other is through

$$x_{ij} = \frac{(d_{ij} - u_{ij})}{n} \quad (2)$$

with the n points given by $(x_{i1}, \dots, x_{im})$ with $i = 1, \dots, n$, where u_{ij} are independent random variables with a common uniform distribution on $(0, 1]$. The difference between the two methods can be seen as follows. When projected onto each of the m variables, both methods have the property that one and only one of the n design points fall within each of the n small intervals defined by $[0, 1/n), [1/n, 2/n), \dots, [(n-1)/n, 1]$. The first method gives the midpoints of these intervals while the second gives the points that are uniformly distributed in their corresponding intervals.

Example 1 The following are two Latin hypercubes of $n = 5$ runs for $m = 2$ factors.

D_1		D_2	
1	3	1	2
2	2	2	5
3	1	3	3
4	4	4	1
5	5	5	4

Their graphical representations are given in Figure 1. Although they are both Latin hypercubes, design D_2 provides a better coverage of the design region than design D_1 . This raises the need of

2 Latin Hypercube Designs

Figure 1 The graphical representations of the two Latin hypercubes in Example 1

developing methods for selecting better Latin hypercubes. We will return to this issue in the section titled “Selecting Good Latin Hypercubes”.

Latin hypercubes are very easy to generate. Simply combining several permutations of $1, \dots, n$, one obtains a Latin hypercube. There is no restriction whatsoever on the run size n and the number m of factors. Since a Latin hypercube has n distinct levels in each of its factors, it achieves the maximum uniformity in each univariate margin. Two useful properties follow from this simple fact. Because of the maximum number of levels, a Latin hypercube presents the experimenter with the opportunity of modeling the complex dependence of the response variable on each of the input variables. Because there are no repeated levels in each factor, a Latin hypercube necessarily has no repeated runs. In computer experiments, a physical mechanism is modeled using a complex deterministic function which is implemented *via* a computer code. Running the computer code twice at the same setting of input variables produces the same output, and therefore using repeated runs in computer experiments is a waste of resources.

By definition, a Latin hypercube does not promise any property in two- or higher-dimensional margins, as clearly demonstrated in Example 1. It is therefore up to the user to find the “right permutations” so that the resulting design has certain desirable properties in two or higher dimensions. One simple strategy is to use a random Latin hypercube in which the permutations are selected randomly. This helps eliminate the possible systematic patterns in the resulting design but there is no guarantee that the design will perform well in terms of other useful design criteria. The next section will look at some of the useful ideas for finding “good” Latin

hypercubes.

Latin hypercube sampling is a sampling method based on Latin hypercube designs. When some of the input factors are environmental variables and therefore follow some continuous distributions, it is desirable that the selected inputs mimic these distributions. The methods as given in equations (1) and (2) are well suited if these environmental variables follow a uniform distribution. If the j th factor follows a continuous distribution with a cumulative distribution function $F_j(x)$, then the inputs for that factor can be selected *via* the familiar quantile transformation $F_j^{-1}(x_{ij})$, where x_{ij} is given by either equation (1) or (2). The design region in this case depends on $F_j(x)$ and takes a more general form than $[0, 1]^m$. In addition to matching the marginal distributions, effort can be made to induce desired correlations among the input variables [5].

When used in numerical integration, Latin hypercube sampling achieves a variance reduction compared with the simplest Monte Carlo integration. The problem here is to find $\mu = \int_{[0,1]^m} f(x_1, \dots, x_m) dx_1 \cdots dx_m$. Let $X_1, \dots, X_m$ be independent uniform random variables on $[0, 1]$. Then $\mu = E(Y)$, where $Y = f(X_1, \dots, X_m)$. The simplest Monte Carlo method is to use $\bar{Y} = n^{-1} \sum_{i=1}^n Y_i$ to approximate μ , where $Y_i = f(X_{i1}, \dots, X_{im})$ with X_{ij} 's being mn independent uniform random variables on $[0, 1]$. Clearly, $E(\bar{Y}) = \mu$ and $\text{Var}(\bar{Y}) = n^{-1} \text{Var}(Y)$. Latin hypercube sampling also uses $\bar{Y} = n^{-1} \sum_{i=1}^n Y_i$ to estimate μ , where $Y_i = f(X_{i1}, \dots, X_{im})$ but this time X_{ij} is given by $X_{ij} = n^{-1}(d_{ij} - U_{ij})$ with $D = (d_{ij})$ being a random Latin hypercube and U_{ij} 's are independent uniform random variables on $[0, 1]$. Stein [6] showed that under Latin hypercube sampling, the estimator $\bar{Y}$ is still unbiased and has a

variance given by

$$\text{Var}(\bar{Y}) = n^{-1}\text{Var}(Z) + o(n^{-1}) \quad (3)$$

where $Z = Y - \mu - \sum_{j=1}^m [E(Y|X_j) - \mu]$. Since $\text{Var}(Y) = \sum_{j=1}^m \text{Var}[E(Y|X_j)] + \text{Var}(Z)$, Latin hypercube sampling has a smaller variance than the simplest Monte Carlo.

Selecting Good Latin Hypercubes

Latin hypercubes are a very rich class of designs. Although all Latin hypercubes enjoy an attractive property in terms of uniformity of the projected design points on each univariate margin, some Latin hypercubes have better properties in higher dimensions while others do not. It is therefore highly desirable to develop methods for selecting Latin hypercubes that perform well in terms of other criteria such as those of orthogonality or space filling. We briefly discuss two sets of ideas that are useful for this purpose. The first set of ideas aims at Latin hypercubes with better space-filling properties. The second set of ideas focuses on finding orthogonal or nearly orthogonal Latin hypercubes.

Space-Filling Latin Hypercubes

A Latin hypercube will provide a good coverage of the design region if all the points are farther apart, that is, no two points are too close to each other. This idea can be formally developed using the maximin distance criterion, according to which designs should be selected by maximizing $\min_{i \neq j} d(p_i, p_j)$, where $d(p_i, p_j)$ denotes the distance between design points p_i and p_j . Euclidean distance is commonly used but other distance measures are also useful. See Johnson *et al.* [7] for a general discussion on maximin and related minimax distance designs. The use of the maximin distance criterion for selecting Latin hypercubes was thoroughly explored by Morris and Mitchell [8].

Orthogonal arrays (see **Orthogonal Arrays**) are very useful designs for physical factorial experiments with and without blocking. A comprehensive treatment of orthogonal arrays is given by Hedayat *et al.* [9]. When used to construct Latin hypercubes, orthogonal arrays give rise to a class of good Latin hypercubes, namely orthogonal array

(OA)-based Latin hypercubes. An OA-based Latin hypercube is a Latin hypercube that becomes an orthogonal array after the levels are properly grouped [10]. To be more specific, an OA-based Latin hypercube $D = (d_{ij})$ of n runs has the property that $A = (a_{ij})$ where $a_{ij} = g(d_{ij})$ is an s -level orthogonal array of $n = ks$ runs, where $g(x) = j$ for $(j-1)k + 1 \leq x \leq jk$. OA-based Latin hypercubes inherit the t -dimensional space-filling property of orthogonal arrays of strength t . To illustrate, we first generate a random Latin hypercube with $n = 25$ runs and $m = 3$ factors, and then generate a random OA-based Latin hypercube also with $n = 25$ runs and $m = 3$ factors, using a five-level orthogonal array of strength 2. To save space, we omit the design matrices, and provide only the pairwise plots of the two designs in Figure 2. The OA-based Latin hypercube as in Figure 2(b) clearly outperforms the Latin hypercube in Figure 2(a) in terms of filling two-dimensional projection spaces.

Orthogonal Latin Hypercubes

A Latin hypercube is said to be orthogonal if the correlation between any two of its columns is zero and nearly orthogonal if the pairwise correlations are all small. The idea of considering nearly orthogonal Latin hypercubes dates back to Iman and Conover [5], who proposed a method for finding nearly orthogonal Latin hypercubes using Cholesky decomposition. Owen [11] developed a more effective algorithm for this purpose on the basis of the Gram–Schmidt orthogonalization. Tang [12] extended Owen’s algorithm to the situations where the correlations of higher orders are to be minimized.

Latin hypercubes that are exactly orthogonal were first formally studied by Ye [13], who constructed a class of orthogonal Latin hypercubes with $n = 2^k$ runs and $m = 2k - 2$ factors. For example, when $k = 4$, his construction gives an orthogonal Latin hypercube of 16 runs for six factors. Note that the ratio m/n becomes very small even for moderately large k . The orthogonal Latin hypercubes constructed by Steinberg and Lin [14] have a large ratio m/n ; the price is the more severe restriction on the run size n , which now has the form $n = 2^{2^k}$, where k is an integer. Related work in this connection is that of Butler [15], who constructed Latin hypercubes that are orthogonal with respect to models based on trigonometric functions.

Figure 2 (a) Pairwise plots of a random Latin hypercube of 25 runs for three factors, and (b) corresponds to a random OA-based Latin hypercube of the same sizes. The underlying orthogonal array for the OA-based Latin hypercube has 25 runs, five levels, and three factors, and is of strength 2

Latin Squares and Related Experimental Designs

Introduction

A Latin square is an arrangement of v copies of v symbols into a $v \times v$ square so that (a) each symbol occurs once in each row and (b) each symbol occurs once in each column. Three distinct Latin squares of order $v = 4$ are shown in Example 1. Other than for small v , the number of distinct (nonidentical as matrices) Latin squares is not generally known, though it is known that it grows rapidly with v ; see Laywine and Mullen [1, Chapter 1].

Example 1. Three 4×4 Latin squares. These squares are mutually orthogonal

3	4	1	2

Our interest in Latin squares is due to their many uses in designing experiments. Suppose you have the task of comparing the wear of drill bits of four different compositions when used in industrial presses. Each day each of your four press operators will

be given a new bit, with wear to be measured at the day's end; this will be repeated for 4 days. A Latin square can be employed to block out variation associated with operators and with days. Consider the first square in Example 1, and identify rows with operators, columns with days, and symbols with bit compositions. Then operator 1 uses composition 1 on day 1, operator 2 uses composition 3 on day 4, and so on. This design displays a basic fairness of allocation, in that each composition is exposed once to each operator and once to each day. Statistically this implies orthogonal **estimation** of the operator, day, and composition effects. This is but one example of the many adaptations of Latin squares for obtaining good experimental designs that will be explored in this chapter. Before proceeding, one more basic definition is needed. Two Latin squares of order v are said to be *orthogonal* (sometimes called a *Graeco-Latin pair*) if, on superimposing one square upon the other, every ordered pair of symbols occurs in the cells exactly once. Check Example 1 and you will see that every pair of squares has this property; the superimposition of all three squares is displayed in Example 2(I). The set of three squares is *mutually orthogonal*. This combinatorial orthogonality of Latin squares translates into statistical orthogonality of various treatment and **blocking** factors when exploited in an experimental design. Latin square designs are valuable because they provide orthogonal estimation, and because they do so with relatively little experimental material for given numbers of factors and levels.

Latin Squares for Blocking out Two Sources of Nuisance Variation

The drill bit experiment in the section titled “Introduction” illustrates the application of a Latin square as a row–column design for eliminating two sources of nuisance variation. Given a Latin square, let rows denote levels of one blocking factor, columns the levels of a second blocking factor, and symbols the levels of your treatment factor. The result is simultaneously a complete block design (*see Block Designs, Incomplete*) for treatments with respect to the row blocking factor and with respect to the column blocking factor.

Let $d[i, j]$ be the treatment appearing in row i , column j of Latin square d (e.g., $d[2, 4] = 3$ for the first square of Example 1). Denote by Y_{ij} the observation for the run in row i , column j (cell i, j). Analysis of the data is based on this model:

$$Y_{ij} = \mu + \rho_i + \gamma_j + \tau_{d[i, j]} + E_{ij} \quad (1)$$

inducing the skeleton analysis of variance or **ANOVA** (put $s = 1$) in Table 1(I). The design with data ($mm \times 10^{-1}$) and the completed ANOVA table for the drill bit experiment is shown in Table 2. In accordance with a proper **randomization** – for a randomly selected Latin square, randomly permute the rows, then the columns, then the symbols – blocking factors should not be tested. Several randomizers for Latin squares can be found on the web, for example www.edgarweb.org.uk. (For ANOVA basics, *see Analysis of Variance.*)

Use of a Latin square means that each pair of rows, columns, and treatments is statistically orthogonal, one consequence of which is that treatment comparisons are based on unadjusted, or raw, data means. So in the analysis of the drill bit data, the raw means 5.5, 3.9, 5.7, 7.7 are the basis for all treatment comparisons and can be used in any standard multiple comparisons procedure (Tukey, Student–Newman–Keuls (SNK), etc.). The drawbacks to this basic Latin square design arise from the requirement that numbers of rows, columns, and

Table 2 Analysis of a 4×4 Latin square experiment

				Total			$v^2 - 1 = 15$	60.52			

treatments are all equal. What can one do, maintaining orthogonality, if this restriction cannot be met, or if it leaves too few **degrees of freedom** for error? These questions are addressed in the following subsections.

More Rows and Columns

More levels of the row factor and/or column factor can be accommodated by juxtaposing several Latin squares. Given ab Latin squares of order v , arrange them into a rows of b squares each, then “paste” them together to yield an $av \times bv$ row–column design. Any ab Latin squares can be used (even ab copies of the same square). This technique (a) allows some flexibility in numbers of rows and columns while (b) preserving the statistical orthogonality properties of a single Latin square and (c) providing more degrees of freedom for error. If now d denotes the $av \times bv$ design, then the model is still equation (1), and the skeleton ANOVA becomes that in Table 1(II). It is also possible to extract degrees of freedom for treatment $\times$ row and/or treatment $\times$ column interaction, but how much can be done is design specific, that is, depends on the Latin squares that are pasted together.

More Squares

Another possibility for gaining error degrees of freedom is multiple Latin squares. If the drill bit experiment is to be run at m sites, each with its own operator and day-to-day variability, then m Latin squares (identical or different) can be employed. The resulting skeleton ANOVA is in Table 1(VI) (put $s = 1$). Again, the orthogonality properties of a single Latin square are preserved, so that treatment comparisons are based on means.

More EUs per Cell: Semi-Latin Squares and k -depth Latin Squares

The basic Latin square has one experimental unit (EU or run), and thus only one treatment evaluated, per cell. If we can procure $k > 1$ EUs per cell in an $n \times n$ row–column blocking layout, then $v = nk$ treatments can be accommodated in each row and column. The design is a *semi-Latin square*: there are k symbols (treatments) in each cell so that each symbol appears once in each row and once in each column.

Semi-Latin squares can be found as superimpositions of k Latin squares of order n , each square having its own set of distinct symbols. Choice of the k squares depends on which of two reasonable models are employed. For Y_{ijl} the measurement on unit l in cell (i, j) , they are

$$Y_{ijl} = \mu + \rho_i + \gamma_j + \tau_{d[i,j,l]} + E_{ijl} \quad (2)$$

and

$$Y_{ijl} = \mu + \beta_{ij} + \tau_{d[i,j,l]} + E_{ijl} \quad (3)$$

Model (2) is the direct extension of (1), accounting for noise through additive effects for the row and column nuisance factors, while the more detailed model (3) fits a separate noise effect for each cell. The respective ANOVA skeletons are Table 1(III, IV). With model (2), treatment analysis is based on means, a consequence of the orthogonality of treatments to rows and columns. Because treatments need not be orthogonal to cells, treatment analysis with model (3) is adjusted for the cell blocks. There are also fewer error degrees of freedom with model (3). These are the trade-offs for the further variance reduction afforded by the finer blocking structure.

With model (2), any k Latin squares may be superimposed to form the semi-Latin square, for all such choices provide orthogonality of rows, columns, and symbols and so are equally efficient. With model (3), the driving consideration is not the rows or the

4 Latin Squares and Related Experimental Designs

columns, but the cells. The goal is to maximize the efficiency of the block design formed by the cell blocks. So long as $k < n$, the best choice is to superimpose k MOLS, resulting in a *Trojan square*. Example 2(II) is a Trojan square (from Example 2(I) with symbols distinguished). Details on maximal k for $n \times n$ Trojan squares are given in the section titled “Designs based on MOLS”. For $n = 6$, the best semi-Latin square for $k = 2$ is reported in Bailey and Royle [2]. Bailey [3] gives a thorough treatment of semi-Latin squares.

Latin and semi-Latin squares use each treatment once in each row and each column. With k EUs per cell, orthogonality in an $n \times n$ row-column design is maintained if each treatment appears nk/v times in each row and column. A k -depth Latin square is an arrangement of vk copies of v symbols into a $v \times v$ square so that each cell has k symbols, and each symbol occurs k times in each row and in each column.

If when superimposing k Latin squares in the semi-Latin construction above, one takes the symbols to be the same in each square, then one gets a k -depth Latin square (see Example 2(I)). This particular class of designs, while fully efficient for model (2), is inefficient for (3) due to replication of the same treatment within cell blocks. The skeleton ANOVA for model (2) is Table 1(I) with $s = 1$ and an additional $(k - 1)v^2$ degrees of freedom added to error and total.

For model (3), start with an $n \times n$ Latin square and a BIBD for v treatments in n blocks of size k . Place block i in each cell of the Latin square containing symbol i for $i = 1, \dots, n$. The resulting $n \times n$ row-column design with k runs per cell is fully efficient for both models (2) and (3). It is a k -depth Latin square if $n = v$. It is also a *doubly resolvable BIBD*, others of which are cataloged in Preece [4]. Example 2(III) displays $n = v = 3$, $k = 2$. The standard BIBD analysis applies.

Other Numbers of Rows and Columns: Youden Designs

If one drops a single row from a Latin square, the rows of the resulting $(v - 1) \times v$ array are a complete block design, while the columns are a BIBD. This *incomplete Latin square* is one version of a class of designs known as *Youden squares*. A Youden square

is a row-column design with k rows and v columns for which each treatment appears once in each row, and columns are blocks of a BIBD. Every Youden square is an incomplete Latin square, though the converse is not true.

Rows and columns may be added by joining separate Youden designs and Latin squares. Paste columns of t Youden squares into a $k \times tv$ array, then paste at Latin squares as in the section titled “More Rows and Columns”, to produce a $(k + av) \times tv$ row-column design called a *regular generalized Youden design*. With the standard row-column model (1) the skeleton ANOVA is Table 1(V). Since treatments are orthogonal to rows, the treatment adjustment is for columns only.

Here is the general idea. Start with any **incomplete block** design, with v treatments in b blocks of size k . Thinking of the blocks as columns, paste them into a $k \times b$ row-column array. If the treatments are equally replicated and if b is a multiple of v (so $b = tv$ for some t), then the treatments can be ordered within the columns so that each treatment appears t times in each row. This is now a row-column design with treatments orthogonal to rows; treatment estimates are the same as for the original block design without the row factor. If more rows are needed, it can be extended to a $(k + av) \times tv$ row-column design using Latin squares as explained above and with the same skeleton ANOVA.

Designs Based on MOLS

The Trojan squares of the section titled “More EUs per Cell: Semi-Latin Squares and k -depth Latin Squares” are built with mutually orthogonal Latin squares, or MOLS. Here other designs based on or related to MOLS will be described. The common theme is that of adding more factors to the designs of the section titled “Latin Squares for Blocking out Two Sources of Nuisance Variation”, maintaining orthogonality without changing the amount of experimental material. But first a basic question must be addressed: how many MOLS of a given order are there? Let $N(v)$ be the largest number of MOLS of order v . Then $N(v) \leq v - 1$ for every v , and $N(v) = v - 1$ for v that is a prime number or a power of a prime number. Example 1 provides $N(4) = 3$ MOLS of order 4. While upper bounds sharper than $v - 1$ are known for some other v , and $N(v) \geq 2$

for all $v > 6$, determining the exact value of $N(v)$ is a daunting (to say the least) combinatorial problem. When $v \leq 20$ is not a prime power, it is known that $N(6) = 1$, $N(10) \geq 2$, $N(12) \geq 5$, $N(14) \geq 3$, $N(15) \geq 4$, $N(18) \geq 3$, and $N(20) \geq 4$. For a catalog of known MOLS for every $v \leq 56$ along with further results, see Abel *et al.* [5].

Row-column Designs with More Blocking and/or Treatment Factors

Let's introduce a third blocking factor, four suppliers of parts to be drilled, in the drill bit experiment described in the section titled "Introduction". The original design, with rows for operators, columns for days, and symbols for drill bits, is the first Latin square in Example 1. Let the levels of supplier be the symbols in the second square. Superimposing the two squares, we see, for instance, that operator 2 on day 4 uses drill bit composition 3 on parts from supplier 2. The pair of MOLS means that each supplier's parts are used once with each bit type, once on each day, and once by each operator. That is, the supplier factor is orthogonal to the three factors operator, day, and bit type (which, as we already know, are orthogonal to one another). The third blocking factor has been introduced without requiring any further experimental runs, and without changing the fact that treatment comparisons are based on treatment averages.

The example shows that two superimposed MOLS provide a design for comparing v treatments using v^2 runs subject to three v -level blocking factors. In the same way, s superimposed MOLS provide a design comparing v treatments using v^2 runs subject to $s + 1$ v -level blocking factors; effects of all factors are orthogonal to one another. For the drill bit example, the symbols in the third square of Example 1, used as levels of a fourth blocking factor, produce the design in Example 2(I).

Another advantage of the orthogonality is that any of the blocking factors could alternatively be used as a treatment factor, so long as estimation of treatment interactions is not required. Thus s MOLS are designs for f v -level treatment factors using v^2 runs subject to $s + 2 - f$ v -level blocking factors, for any $1 \leq f \leq s + 2$. Table 1(I) shows the skeleton ANOVA. Each of the first $s + 2$ rows is identified with either a blocking factor or a treatment factor. Because only main effects, and no interactions, of treatment factors

are estimable, these are called (blocked) *main-effects plans*. The case $f = s + 2$ demonstrates that s MOLS are equivalent to an **orthogonal array** of strength 2 with v^2 runs on $s + 2$ v -level factors.

More Rows and Columns: Orthogonal F -rectangles

The designs of the section titled "More Rows and Columns" can also incorporate more blocking (or treatment) factors through orthogonal mates. An $av \times bv$ array with one symbol per cell is an F rectangle (F square if $a = b$) if each of v symbols occurs b times in each row and a times in each column; the designs of the section titled "More Rows and Columns" are F rectangles. Two F rectangles are orthogonal if superimposition produces each ordered pair of symbols in ab cells. Mutually orthogonal F rectangles admit the same applications as described for MOLS in the section title "Row-Column Designs with More Blocking and/or Treatment Factors", with now the row and column factors having av and bv levels (and thus $av - 1$ and $bv - 1$ df), respectively. A set of s mutually orthogonal F rectangles is equivalent to a mixed-level orthogonal array of strength 2 with $s + 2$ columns. For examples of mutually orthogonal F squares, and for further references, see Laywine and Mullen [6].

More Squares: Orthogonal Collections of Latin Squares

Orthogonal mates can likewise be found for sets of m Latin squares in the section titled "More Squares". A collection of s ordered sets, each containing m Latin squares of order v , is an (s, m) *orthogonal collection* if, on superimposition of the m corresponding squares of any two sets, each ordered pair of symbols occurs m times. MOLS are the special case $m = 1$.

The symbols in a given set of m squares, the same for each of these m squares, are levels of additional v -level treatment factors. With $s = 2$ and $m = 3$, for example, the drill bit experiment could be run at 3 sites, each with its own days and operators, but evaluating levels of two four-level treatment factors: drill bit composition and (say) lubricant. The skeleton ANOVA is Table 1(VI). Designs and further details may be found in Morgan [7], where in particular it is seen that four orthogonal six-level factors can be accommodated in two 6×6 squares. As seen above

($N(6) = 1$), only one such factor is possible in one 6×6 square.

More EUs per cell

It is not possible to add orthogonal v -level treatment factors to semi-Latin squares, for they have less than v_2 EU's. However, this can be done for the other designs in the section titled "More EUs per Cell: Semi-Latin Squares and k -depth Latin Squares".

Starting with an (s, k) -orthogonal collection of Latin squares of order v , we can make a $v \times v$ row-column design with k units per cell for s orthogonal treatment factors. The symbol in cell (i, j) of square u ($= 1, \dots, k$) in set w ($= 1, \dots, s$) of the collection is the level of factor w that appears on unit u in cell (i, j) of our design. If $s = 1$ this is a k -depth Latin square of the section titled "More EUs per Cell: Semi-Latin Squares and k -Depth Latin Squares"; if $k = 1$ it is the design of the section titled "Row-Column Designs with More Blocking and/or Treatment Factors". Relative to the k -depth square, $s - 1$ additional orthogonal treatment factors have been incorporated; relative to a set of MOLS, incorporating k EUs per cell has increased error degrees of freedom by $(k - 1)v^2$. The skeleton ANOVA is Table 1(I) with an additional $(k - 1)v^2$ degrees of freedom added to error and total. Example 2(IV) has five four-level factors in a 4×4 design with $k = 2$ units per cell. Like a single k -depth Latin square, this design is fully efficient for model (2) but inefficient for model (3).

The design in the last paragraph of the section titled "More EUs per Cell: Semi-Latin Squares and k -depth Latin Squares" can accommodate orthogonal treatment factors by replacing the BIBD with an orthogonal set of BIBDs. Orthogonal sets of BIBDs may be found in Morgan and Uddin [8]. The orthogonality of treatment factors is after adjusting for the cell blocking factor in model (3).

Orthogonal Youden designs

It is sometimes possible to add orthogonal treatment factors to regular generalized Youden designs. Here, too, the orthogonality of treatment factors is after adjusting for the column blocks (see Morgan and Uddin [8]).

Discussion

This paper provides an overview of the chief uses of Latin squares for designs for industrial and manufacturing experiments. The designs combine orthogonal estimation with an economy of experimental units, providing for both blocking and treatment factors. While the variants presented offer flexibility in numbers of rows, columns, factors, and so on, there are many experimental possibilities that are not amenable to the inherent restrictions of Latin squares. In such cases, orthogonality is sacrificed.

Specialized Latin squares have been employed in experimental situations not discussed above. *Row-complete Latin squares*, including *Williams squares*, are used as crossover designs (also called *changeover* or *repeated measures designs*); see Hinkelmann and Kempthorne [9, Chapter 19]. *Quasi-complete Latin squares* are row-column designs with nondirectional neighbor balance as discussed in Bailey [10] and Morgan [11]. Hedayat [12] examines designs based on *self-orthogonal Latin squares*. *Gerechte squares* [13] are Latin squares with a third blocking factor orthogonal to treatments but not to rows or columns. When $v = 9$ they include what are popularly known as *completed Sudoku squares*.

Lenth's Method for the Analysis of Unreplicated Experiments

Introduction

Consider a 2^{7-4} experimental design (see **Fractional Factorial Designs**) involving seven factors, each at two levels, and only eight experimental runs. This is an example of a saturated experiment, in that we must estimate eight parameters (seven main effects plus the mean), leaving no **degrees of freedom** for error.

The analysis of such experiments has historically been rather subjective. A popular method has been that of Daniel [1] (see **Half-Normal Plot**), whereby the absolute values of the seven main-effect estimates are plotted against half-normal scores (i.e., equally spaced **quantiles** of the half-normal distribution). If all the true main effects are zero, these points should fall near a straight line; however, if there is a small number of “active” (nonzero) effects while the remaining ones are inactive, the inactive ones should follow a straight line and the active ones should look like **outliers**.

The half-normal-plot method requires one to make a judgment about what is an outlier and what is not. In an effort to remove this element of subjectivity, Lenth [2] proposed a method for estimating a standard-error-like quantity, called the pseudo standard error or PSE. The effects are then judged relative to the PSE to decide whether there is enough evidence for them to be deemed active.

Both the Daniels method and the Lenth method rely on the concept of “effect sparsity” – that only a few effects are active and the rest are inactive. This concept is discussed more rigorously in Box and Meyer [3], along with another objective method for analyzing such experiments.

The Method

Lenth's method assumes that we have m independent contrast or effect estimates and that they all have the same variance τ^2 . In an orthogonal two-level experiment on N observations, for example, each

contrast has the form $c = \bar{y}_+ - \bar{y}_-$, where $\bar{y}_+$ is the average of the $N/2$ observations at the “high” level of a factor and $\bar{y}_-$ is the average of the $N/2$ observations at the “low” level. Each such contrast has variance $\tau^2 = 4\sigma^2/N$, where σ^2 is the error variance. Let $c_1, c_2, \dots, c_m$ denote the m contrast estimates. Usually, owing to the fact that the model is saturated, we have $m = N - 1$.

The computation involves two stages. First, let

$$s_0 = 1.5 \cdot \text{median} \{|c_j|\} \quad (1)$$

Then, let

$$PSE = 1.5 \cdot \text{median} \{|c_j| : |c_j| \leq 2.5s_0\} \quad (2)$$

Note that the second step is just like the first, except that we exclude those effects that exceed $2.5s_0$ in absolute value. PSE is termed the pseudo standard error, and it is an estimate of τ .

Once the PSE is obtained, one can multiply it by a factor from Table 1 to obtain a margin of error (ME) for the contrasts. Contrasts that exceed the ME in absolute value are deemed active at the 5% **significance level**. Alternatively, one may compute a simultaneous margin of error (SME) using a different factor from Table 1. The distinction is that there is at most a 5% chance that one individual inactive contrast will exceed the ME, while there is at most a 5% chance that *any* inactive contrast will exceed the SME.

The recommended practice is to display the contrasts in a bar chart or a **Pareto** chart, with decision lines added for the ME and the SME (see the example below). A contrast that extends beyond the SME line is clearly an active effect. One that exceeds the ME but not the SME should be viewed with some caution, as it may be an artifact of testing several contrasts.

Some software implementations of Lenth's method produce a **half-normal plot** of the contrasts with a reference line having a slope based on the

Table 1 Multipliers to obtain the ME and SME at the $\alpha = 0.05$ level

m	for ME	for SME	m	for ME	for SME
7	2.297	4.867	19	2.120	4.118
8	2.201	4.868	23	2.097	4.017
11	2.211	4.438	26	2.082	3.985
15	2.156	4.240	27	2.077	3.964
17	2.138	4.164	31	2.064	3.925

2 Lenth's Method-Analysis of Unreplicated Experiments

PSE; however, this is a poor alternative to the bar chart and is not recommended because it does not show the decision thresholds.

The values in Table 1 are excerpted from tables in Ye and Hamada [4] that cover several additional values of m and significance levels other than .05.

Example Box *et al.* [5] present data from an eight-run experiment involving seven two-level factors. The response variable is the time it takes to climb a particular hill on a bicycle, and the factors are such things as seat height, dynamo off or on, and so on. The data are displayed in Table 2. The factor levels shown in the headings correspond to the respective labels “–” and “+” in the table. The final row gives the contrast estimates c_j . (To improve clarity, the factor levels are altered from those in the reference.)

The calculations are as follows. The median of the absolute contrasts $\{3.5, 12, 1.0, 22.5, 0.5, 1.0, 2.5\}$ is 2.5; hence, $s_0 = 1.5 \times 2.5 = 3.75$ and $2.5s_0 = 9.375$. Since two of the seven contrasts exceed this bound, we compute the PSE from the remaining five: $PSE = 1.5 \cdot \text{median}\{3.5, 1.0, .5, 1.0, 2.5\} = 1.5 \times 1 = 1.5$. Now, using Table 1 with $m = 7$, we have $ME = 2.297 \times 1.5 = 3.45$ and $SME = 4.867 \times 1.5 = 7.30$. Figure 1 shows a bar chart of the contrasts with reference lines added for $\pm ME$ and $\pm SME$.

The contrasts for gear and dynamo exceed the SME, and so they are identified as active effects. Both are positive effects, meaning that a higher gear ratio and the presence of the dynamo both increase the expected time to climb the hill. The contrast for seat barely surpasses the ME in the negative direction, providing a hint that having the seat up might reduce the time. However, this contrast does not surpass the

Figure 1 Bar chart of the contrast estimates for the bicycle example

SME, which means that if we adjust for multiple testing, it is not identified as active.

Discussion

Subsequent to the publication of [2], it has been found that the critical values suggested there are too conservative; hence, the tables in [4], excerpted in Table 1, are preferable. These critical values are based on the complete null case – where all the contrasts are assumed inactive. When one or more of the contrasts are actually active, that tends to inflate PSE somewhat, making the procedure somewhat conservative. It grows more conservative as the number of truly active effects increases, and is most conservative when the magnitude of the active effect is only moderate (less than 2τ or so). (Very large active effects lead to large contrasts that have a very high chance of exceeding $2.5s_0$ and thus being discarded in the second step of computation.)

The main advantage of Lenth's method is its simplicity and ease of use, making it easy to incorporate

Table 2 Data from the bicycle experiment

Time (s)	Seat down/up	Dynamo no/yes	Handlebars down/up	Gear low/med	Raincoat off/on	Breakfast no/yes	Tires soft/hard
50	–	–	–	–	–	+	+
52	–	–	+	–	+	–	–
88	–	+	–	+	–	–	–
83	–	+	+	+	+	+	+
71	+	–	–	+	+	+	–
69	+	–	+	+	–	–	+
59	+	+	–	–	+	–	+
60	+	+	+	–	–	+	–
Contrast:	–3.5	12.0	–1.0	22.5	–0.5	–1.0	–2.5

into programs or spreadsheet computations, or even to do by hand. Its main disadvantage is that it is based on a restrictive set of assumptions: independent contrast estimates that all have the same variance.

Lenth's method should not be used in replicated experiments, where the standard error can be estimated more efficiently by traditional analysis-of-variance methods.

There are other objective methods that can be used instead of Lenth's method. Most notable among these is the Bayesian method of Box and Meyer [3], which (unlike the Lenth method) is extensible to a broad class of regression variable-selection problems (see [6]). There is also a formulation in [7] of the Box-Meyer method that analyzes which factors (rather than which effects) are active. A survey and **Monte Carlo** comparison of several methods is given in [8].

RUSSELL V. LENTH

Main Effects

The Cell-Means Definition

In a *factorial experiment* (see **Factorial Experiments**), the *main effect* of a given factor, say F , is a measure of the average change in expected response that occurs when the level of factor F is changed. Here the “average” is taken over all other factors in the experiment. We will first develop this idea through several examples, and then follow with a formal definition.

The 2 × 2 Experiment. Here there are two factors, say A and B , each measured at two levels, which we may denote by 0 and 1. Let us suppose that the true (theoretical) mean responses to the four treatment combinations are given in the following table:

		Levels of B	
		0	1
Levels of A	0	4	6
	1	8	9

The treatment combination (0, 0) – A and B both at level 0 – is assumed to yield a mean response of 4, and similarly for the other treatment combinations (or *cells*). The change in the average expected response due to change in the level of A is

$$\frac{4 + 6}{2} - \frac{8 + 9}{2} = -3.5 \quad (1)$$

(or 3.5 if we change in the opposite direction). Thus a measure of the main effect of A is -3.5 units. Similarly, the main effect of B is -1.5 .

Note that if we were to replace the 9 by a 6 in this example, we would calculate the main effect of B to be 0. This would not mean that B has no effect on responses, but merely that it affects responses only through its *interaction* (see **Interactions**) with A . We may say in this case that B has no main effect, or that the main effect of B is absent.

A simulated experiment based on the theoretical values given above might yield the following data, with two observations per cell. Cell averages, which are least-squares estimates of the true mean responses

above, are given in parentheses:

		0	1
	0	4.75, 3.79 (4.270)	6.24, 5.79 (6.015)
	1	7.83, 7.82 (7.825)	10.37, 8.83 (9.600)

The main effect of A calculated in equation (1) could thus be estimated by

$$\frac{4.270 + 6.015}{2} - \frac{7.825 + 9.600}{2} = -3.57 \quad (2)$$

The corresponding main effect of B would be estimated as -1.76 . The *analysis of variance* in Table 1 (see **Analysis of Variance**) confirms that the main effects of A and B are significant – that is, that the estimated values are significantly different from 0.

To formulate our ideas more generally, we denote the true mean response to treatment combination $t = (i, j)$ by μ_{ij} . We have described the main effect of factor A as the difference between the average response to level “0”, or $(\mu_{00} + \mu_{01})/2$, and that to level “1” of A , namely $(\mu_{10} + \mu_{11})/2$, that is,

$$\frac{\mu_{00} + \mu_{01}}{2} - \frac{\mu_{10} + \mu_{11}}{2} \quad (3)$$

(see, e.g. [1, Chapter 10]). Of course, we could subtract in the opposite order as well. In fact, one often describes this effect by ignoring the factors of $1/2$ and writing simply:

$$\mu_{00} + \mu_{01} - \mu_{10} - \mu_{11} \quad (4)$$

Expressions such as (3) and (4) are called *contrasts*, as they contrast the responses to (in this case) the different levels of factor A . We say that A *has no main effect*, or that *the main effect of A is absent*, if any of these expressions equals 0, in which case they all do. We also note that the **sum of squares** (SS) for a contrast is not affected if we multiply the contrast

Table 1 Analysis of variance for the 2 × 2 example

Source	df	SS	MS	F	p

Interaction	1	0.0004	0.0004	0.00	0.976
Error	4	1.7479	0.4370	–	–
Total	7	33.4334			

2 Main Effects

by a nonzero constant (such as -1 or $1/2$). Thus the main effect of factor A may simply be defined by the contrast (equation (4)). We note that the coefficients in this expression are $+1$ where $i = 0$, and -1 where $i = 1$, independent of the value of j (the level of B).

In similar fashion, the main effect of factor B is defined as the contrast

$$\mu_{00} - \mu_{01} + \mu_{10} - \mu_{11} \quad (5)$$

Here the values of the coefficients are independent of the value of i (the level of A). We note that the interaction of A and B is also given by a contrast, namely

$$\mu_{00} - \mu_{01} - \mu_{10} + \mu_{11} \quad (6)$$

If this equals 0, then $\mu_{00} - \mu_{01} = \mu_{10} - \mu_{11}$, so that changing the level of B alters μ_{ij} by the same amount at each level of A . In this case we say that *interaction is absent*. We see that the coefficients of equation (6) depend on the levels of *both* factors.

The $2 \times 2 \times 2$ Experiment. Here we have three factors, say A , B , and C , each at two levels. The treatment combinations are ordered triples $t = (i, j, k)$, where k denotes the level of factor C . The contrasts for the main effects are often given *via* a table such as the following:

Cell	000	001	010	011	100	101	110	111
A	1	1	1	1	-1	-1	-1	-1
B	1	1	-1	-1	1	1	-1	-1
C	1	-1	1	-1	1	-1	1	-1

The main effect of C , for example, is defined by the contrast

$$\begin{aligned} &\mu_{000} - \mu_{001} + \mu_{010} - \mu_{011} + \mu_{100} \\ &- \mu_{101} + \mu_{110} - \mu_{111} \end{aligned} \quad (7)$$

Some authors prefer to view this as a difference of averages, analogous to equation (3), and so multiply it by $1/4$.

The 2^n Experiment. The extension to four or more two-level factors is handled analogously. Wu and Hamada [2, p. 97] give an example of a $2 \times 2 \times 2 \times 2$ or 2^4 experiment to study the growth of an epitaxial layer on polished silicon wafers. The factors studied are susceptor-rotation method (continuous or oscillating), nozzle position (2 or

6), deposition temperature (1210 or 1220 °C), and deposition time (low or high). From the observations in each treatment combination they calculate an observed average thickness (μm), and use this to estimate the main effect of factor susceptor-rotation method [2 p. 105] by calculating $(1/8)$ (sum of average thicknesses, oscillating $-$ sum of average thicknesses, continuous) $= -0.077$.

This effect turns out not to be statistically significant ($p = 0.439$).

The 2×3 Experiment. This is the simplest example of a factorial experiment with a factor at more than two levels. Here we have two factors, say A and B , such that A has two levels and B has three. The main effect of B must now be described by *two* independent contrasts (we say that it has *2 degrees of freedom* (df)). Denoting the levels of A as before and those of B by 0, 1, and 2, one choice of main effects contrasts is given in the following table, which lists the contrast coefficients:

Cell	00	01	02	10	11	12
A	1	1	1	-1	-1	-1
B	1	-1	0	1	-1	0
	1	0	-1	1	0	-1

Other choices of contrasts are possible. As before, the coefficients of the A contrast do not depend on the level of B , and those of the two B contrasts do not depend on the level of A . As we have noted, the choice of contrasts does not affect the sums of squares for main effects, which thus provide an overall summary of the intensity of each main effect. (This also applies in so-called nonorthogonal designs, although there the sums of squares must be adjusted.)

The general case. If factor F is measured at s levels, then it has $s - 1$ df. This means that its main effect is described by a set of $s - 1$ contrasts in cell means. The main effect of F is said to be absent if all these contrasts are zero. We now give a more precise definition of the contrasts belonging to a main effect.

A factorial experiment consists of n factors, the i th factor measured at s_i levels, so that there are $s_1 \times \dots \times s_n$ *treatment combinations* or *cells*. We let T be the set of treatment combinations. Each $t \in T$ is a multi-index or n -tuple (e.g., $t = (i, j, k)$ if $n = 3$), and we denote the corresponding *cell mean* by μ_t .

A *contrast* is an expression $\sum_{t \in T} c_t \mu_t$ such that the coefficients c_t add up to zero. The least-squares estimate of a contrast is calculated by replacing cell means by observed sample averages.

We say that a contrast $\sum_{t \in T} c_t \mu_t$ *belongs to the main effect of the i th factor* if the coefficients c_t do not depend on any factors other than the i th [3]. Contrasts belonging to interactions may be defined in similar fashion.

The Factor Effects Parametrization

A different way of defining main effects arises by using a different set of parameters. In the two-factor case, the means μ_{ij} are expressed by the set of equations

$$\mu_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij} \quad (8)$$

This is often accompanied by a set of side conditions of the form

$$\begin{aligned} \sum_i v_i \alpha_i &= 0, & \sum_j w_j \beta_j &= 0, \\ \sum_i v_i \gamma_{ij} &= 0 \quad \text{for each } j, \\ \sum_j w_j \gamma_{ij} &= 0 \quad \text{for each } i \end{aligned} \quad (9)$$

where the weights v_i and w_j are nonnegative and sum respectively to unity. In the presence of these side conditions, μ represents an overall level of response, α_i is the *main effect of the i th level of A* , β_j is the *main effect of the j th level of B* , and γ_{ij} is the *interaction of the i th level of A with the j th level of B* . According to Scheffé, “if the set of constants $\{\mu, \alpha_i, \beta_j, \gamma_{ij}\}$ satisfies (condition (8)) this is not sufficient for them to be the general mean, main effects, and interactions, unless the side conditions (9) are satisfied” [7, p. 92].

The model $E(Y_{ij}) = \mu + \alpha_i + \beta_j + \gamma_{ij}$ is sometimes called a *factor effects model* [5], while $E(Y_{ij}) = \mu_{ij}$ is a *cell means model* [6].

With the constraints (9) in place, one may solve equation (8) for the factor effects parameters. It is not hard to see that the resulting equations express these parameters as contrasts in the cell means μ_{ij} . But do the contrasts expressing α_i belong to the main effect for A , and those for β_j to B , in our earlier sense? The

answer is yes if, and only if, one uses equal weights ($v_1 = \dots = v_a = 1/a$ and $w_1 = \dots = w_b = 1/b$). In this case equation (9) reduces to the more familiar “zero-sum” constraints

$$\begin{aligned} \sum_i \alpha_i &= 0, & \sum_j \beta_j &= 0, \\ \sum_i \gamma_{ij} &= 0 \quad \text{for each } j, \\ \sum_j \gamma_{ij} &= 0 \quad \text{for each } i \end{aligned} \quad (10)$$

For example, solving equation (8) in the 2×3 case using the zero-sum constraints, we find that

$$\begin{aligned} \mu &= \left(\frac{1}{6}\right) \mu_{..} \\ \alpha_1 &= \left(\frac{1}{6}\right) (\mu_{.1} - \mu_{.2}) \\ \beta_1 &= \left(\frac{1}{6}\right) (2\mu_{.1} - \mu_{.2} - \mu_{.3}) \\ \beta_2 &= \left(\frac{1}{6}\right) (-\mu_{.1} + 2\mu_{.2} - \mu_{.3}) \\ \gamma_{11} &= \left(\frac{1}{6}\right) (2\mu_{11} - \mu_{12} - \mu_{13} - 2\mu_{21} + \mu_{22} + \mu_{23}) \\ \gamma_{12} &= \left(\frac{1}{6}\right) (-\mu_{11} + 2\mu_{12} - \mu_{13} \\ &\quad + \mu_{21} - 2\mu_{22} + \mu_{23}) \end{aligned} \quad (11)$$

where, as usual, $\mu_{i.} = \sum_j \mu_{ij}$, $\mu_{.j} = \sum_i \mu_{ij}$, and $\mu_{..} = \sum_i \sum_j \mu_{ij}$. The other parameters are obtained from equation (11) by applying the constraints; for example, $\alpha_2 = -\alpha_1$. It is evident that the contrasts for α_1 and α_2 belong to the main effect of A , and those of the β_j to B .

Main Effects in Fractional Factorial Experiments

A subset $S \subset T$ of the set of treatment combinations in a factorial experiment is a *fractional factorial* (see **Fractional Factorial Designs**) experiment, or *fraction*. Viewed as an *orthogonal array* (see **Orthogonal Arrays**), a fraction has a given *strength* t . If $t \geq 1$, then the restriction of each main-effect contrast to the subset S will still be a contrast, and each main effect will still be represented by the same df. For example, in the 2^3 experiment above, suppose $S = \{000, 011, 101, 110\}$, a fraction of strength 2. Then in S the contrast (equation (7)) for the main effect of C becomes

$$\mu_{000} - \mu_{011} - \mu_{101} + \mu_{110} \quad (12)$$

4 Main Effects

If in addition $t \geq 2$, then contrasts belonging to different main effects will also be mutually orthogonal. We may take these restricted contrasts as defining the main effects in the fraction [7].

One difficulty that arises in a fraction is that restricted contrasts belonging to a main effect may be the same as those belonging to an interaction. We say that the main effect is *aliased* (see **Aliasing in Fractional Designs**) with the interaction in the fraction. If one assumes in addition that interactions are absent, then we say that the main effects are *measurable* in the fraction [8].

Main Effect Designs

Introduction

In the planning stages of any experimental study, an investigator must determine which experimental factors to include in the study. An experimental factor is a variable that is studied in the experiment and believed to potentially have an effect on a response variable of interest. The values of a factor at which experimental runs are conducted are called the *levels of the factor*. During an experimental study, the levels of each factor are usually experimentally changed during different runs of the experiment so that the direct effects of each factor (called *main effects* (MEs)) on the response can be assessed as well as how factors affect the response in combination (called *interactions*, see **Interactions**). However, when the list of potential experimental factors is long, it is important in the early stages of an experimental process to identify those experimental factors which do in fact have an influential effect on a response variable and to screen out those that do not. This is the primary purpose of screening experiments (see **Screening Designs**). One type of screening experiment which is useful in such situations is called a *main effects design*. ME designs focus on the identification of influential MEs rather than interactions and are particularly useful for experimental studies in which the initial list of experimental factors is large compared to the number of runs that can be made in the initial screening experiment. In this article, we consider the use and construction of ME designs.

In an ME design, a factor may be either quantitative or qualitative. Quantitative factors such as time or age can assume all values on a continuous scale. Qualitative factors such as different machine types or different crop varieties have levels which can only assume discrete values and typically cannot be rank ordered. The selection of levels for factors to include in an experiment is somewhat subjective. For example, if a quantitative factor is believed to have primarily a linear effect on a response, then only two levels of the factor may be selected whereas if it is believed that a quantitative factor may effect a response nonlinearly, then three or more levels may be selected to allow for detection of a factor curvature effect. There is usually much less choice in the selection of levels of a

qualitative factor as the levels of such a factor are determined by the qualitative nature of the variable.

The most popular screening experiments in use today are factorial experiments (see **Factorial Experiments**). A factorial experiment is one in which the treatments consist of different combinations of experimental factor levels. ME designs are one type of factorial experiment.

Further Notation and Model

In this article we consider experimental situations in which m factors are to be studied using a factorial experiment with N runs. We shall use d to denote a design which can be used in such a situation and interchangeably represent d by an $N \times m$ matrix $X_d = (\mathbf{x}_{d1}, \dots, \mathbf{x}_{dm}) = (x_{dij})$ whose i th row corresponds to run i and j th column corresponds to factor j . If factor j has s_j levels, then the entries in column j of X_d will consist of symbols $1, 2, \dots, s_j$ with $x_{dij} = t \in \{1, 2, \dots, s_j\}$ if factor j occurs at level t in run i .

The model used to analyze the data from a given design d is

$$\mathbf{Y} = \beta_0 \mathbf{1}_N + \sum_{i=1}^m X_{di} \beta_i + \boldsymbol{\varepsilon} \quad (1)$$

where $\mathbf{Y}$ is a $N \times 1$ vector of observations, β_0 is an overall mean effect, $\mathbf{1}_N$ is an $N \times 1$ vector of 1's, X_{di} is an $N \times (s_i - 1)$ matrix corresponding to factor i having s_i levels, β_i is an associated set of ME parameters, and $\boldsymbol{\varepsilon}$ is a vector of random error terms whose entries are assumed to be uncorrelated with mean *zero* and constant variance σ^2 . The actual entries of X_{di} usually depend upon whether factor i is a quantitative or qualitative factor. If factor i is a quantitative factor with s_i levels, the entries of X_{di} are usually coded (using orthogonal polynomials) so that all polynomial effects up through degree $s_i - 1$ can be estimated. For example, if factor i has $s_i = 3$ equally spaced factors all occurring in $N/3$ runs, then X_{di} has two columns with entries $-1, 0, 1$ and $1, -2, 1$, respectively, depending on whether factor i occurs at its low, middle or high level. If factor i is a qualitative variable with s_i levels then the entries of X_{di} can be coded in several different ways. We shall assume for convenience that the average effect

2 Main Effect Designs

of factor i is zero which implies one parameterization where column p of X_{di} corresponding to level p , $p = 1, \dots, s_i - 1$, has entries 1 if factor i occurs at level p , -1 if factor i occurs at level s_i and 0 otherwise. Under this parameterization, the parameter corresponding to column p of X_{di} represents the difference in the average response at level p and the overall average. Because we are only interested in estimating MEs for factors, we do not include interaction terms in model (1). We shall say that a design is saturated if $\sum_{i=1}^m (s_i - 1) + 1 = N$ or nearly saturated if $\sum_{i=1}^m (s_i - 1) + 1$ is “close” to N . When ME designs are used as **screening designs**, they are often saturated or nearly saturated. In these situations, the identification of influential effects in model (1) usually depends upon the form of the matrices X_{di} . If the columns of all the X_{di} are orthogonal to one another and the corresponding parameter estimates can be assumed to be normal random variables with equal variances, then graphical methods such as half-normal plots (see **Half-Normal Plot**), can be used to identify significant effects. However, because the use of graphical methods is somewhat subjective in nature, other, more objective, statistical methods have been developed to identify significant effects in these situations, for example, see Hamada and Balakrishnan [1] for a good discussion of available methods such as Lenth’s method (see **Lenth’s Method for the Analysis of Unreplicated Experiments**). When the columns of the X_{di} in model (1) are nonorthogonal or are orthogonal but the corresponding parameter estimates do not satisfy the assumptions required for the use of half-normal plots or other available methods, regression analysis and variable selection techniques can be used to identify influential effects.

When using model (1) to analyze the data from a given design d , a useful property for d to have is that of proportional frequencies. In particular, let factors i and j have s_i and s_j levels, respectively, and let n_{pq} be the number of runs in d at level p of factor i and level q of factor j . We say factors i and j have proportional frequencies if for all $p = 1, \dots, s_i$ and $q = 1, \dots, s_j$,

$$n_{pq} = \frac{n_{p.} \cdot n_{.q}}{N} \quad (2)$$

where $n_{p.} = \sum_{l=1}^{s_j} n_{pl}$ and $n_{.q} = \sum_{l=1}^{s_i} n_{lq}$. The property of proportional frequencies was derived by Addelman [2] and insures that any difference between

the averages of observations at two levels of factor i is orthogonal (when considered as a linear combination of the observations) to any difference between the averages of any two levels of factor j . Any design in which all pairs of factors have proportional frequencies is called an *orthogonal main effects (OME) design*. The property of proportional frequencies in an OME design thus makes the **estimation** of OME parameters in model (1) relatively easy. We shall denote an OME design d in N runs having m_i factors with s_i levels, $i = 1, \dots, k$, by $\text{OME}(N, s_1^{m_1} \dots s_k^{m_k})$.

We note that there are no interaction terms included in model (1). This implies the assumption that interaction effects are small compared to MEs. When this assumption is valid, then the model given in equation (1) is useful for identifying significant MEs of factors on a response. When this assumption is invalid, the analysis using model (1) can lead to the identification of some factors as having an influential effect on a response variable when they do not, or, what is worse, lead the experimenter to miss entirely some influential factors. In any case, it is always wise after running an ME screening design to run a follow-up experiment to explore interactions between factors and develop a more detailed model relating the response variable to experimental factors.

Orthogonal Array Main Effect (OAME) Designs

Some of the most popular ME designs used today are the two- and three-level regular **fractional factorial** design, and Plackett–Burman (PB) (see **Plackett–Burman Designs**) designs. However, because these designs are all special cases of orthogonal array (OA) (see **Orthogonal Arrays**) designs of strength two defined below and because these designs are considered elsewhere in this volume we do not consider them here. We also note that OA designs serve as the building blocks for other useful and more general ME designs. We shall henceforth denote an OA design d of strength two in N runs having m_i factors with s_i levels, $i = 1, \dots, k$ by $\text{OAME}(N, s_1^{m_1} \dots s_k^{m_k})$.

Definition 1 Let d be an ME design with $N \times m$ matrix X_d .

Table 1 Orthogonal array main effects designs

36	$2^{35}, 3^1 2^{27}, 3^2 2^{30}, 6^1 3^1 2^{18}, 3^4 2^{13}, 6^2 2^{13}, 9^1 2^{12}, 3^{12} 2^{11}, 6^1 3^2 2^{11}, 6^1 3^8 2^{10}, 6^2 3^1 2^{10}, 6^2 3^4 2^9, 6^3 2^8, 3^{13} 2^4, 6^3 3^1 2^4, 6^1 3^9 2^3, 6^3 3^2 2^3, 6^1 3^{12} 2^2, 6^2 3^5 2^7, 6^2 3^8 2^1, 6^3 3^3 2^1, 4^1 3^{13}, 12^1 3^{12}, 6^3 3^7$

1. We say factors p and q are orthogonal if in columns p and q of X_d each level of factor p occurs equally often with each level of factor q .
2. We say d is an $\text{OAME}(N, s_1^{m_1} \dots s_k^{m_k})$ design of strength two if every pair of factors in d is orthogonal.

Comment The definition of an orthogonal array main effect (OAME) design given above can be extended to that of an OA design of strength t (see **Orthogonal Arrays**). However, because such designs typically require relatively large numbers of runs, we do not consider them here. Also, because we will only be considering OAME designs of strength two, we will henceforth omit any reference to the strength of the designs considered. An excellent reference on the properties and construction of general OA designs is the book *Orthogonal Arrays: Theory and Applications* by Hedayat et al. [3].

We note that in an ME design d , if factors p and q are orthogonal to one another, then factors p and q have the property of proportional frequencies since each level of factor p occurs equally often with each level of factor q . Thus an OAME design

d is clearly an OME design since all pairs of factors in d are orthogonal. Another useful property regarding OAME designs is that it is possible to determine a lower bound for the number of runs required to accommodate all factors (though the bound is not necessarily achievable in all cases). The following theorem can be derived using the property of orthogonality of factors in an OAME design.

Theorem 1 For an $\text{OAME}(N, s_1^{m_1} \dots s_k^{m_k})$ design d , N must be divisible by $s_i s_j$, $i, j = 1, \dots, k$.

Example 1 Suppose an experimental situation requires the use of a design having m_1 factors with three levels and m_2 factors with two levels where $m_1 \geq 2, m_2 \geq 2$. Then, using Theorem 1, any number of runs required for an $\text{OAME}(N, 3^{m_1} 2^{m_2})$ design must have N divisible by $3^2 = 9, 2^2 = 4$, and $3 \times 2 = 6$. Hence, the minimum possible value for N is $N = 36$.

A large number of OAME designs have been constructed using various methods. The largest listing and catalogue of such designs known to the author is available on the web at www.research.att.com/

4 Main Effect Designs

~njas/oadir. This website is maintained by N.J.A. Sloane. Some useful OAME designs having 36 or fewer runs are listed in Table 1. For the construction and actual form of the arrays given in that Table, the reader is referred to the website given earlier.

With regard to the usage of OAME designs, there are certain advantages and disadvantages that should be kept in mind.

Advantages

1. Economy of run size. In a number of situations, an OAME design will allow an experimenter to run a screening experiment using the minimum number of runs required to estimate all or nearly all parameter effects of interest, that is, the OAME design will be saturated or nearly saturated. For example, if a screening experiment requires 18 runs and has eight factors with seven factors having three levels and one factor having two levels, then an $\text{OAME}(18, 3^7 2^1)$ can be used, or if there are four factors having three levels each to be screened in nine runs, then an $\text{OAME}(9, 3^4)$ can be used.
2. Estimates for all ME parameters between different factors can be estimated orthogonally to one another and such estimates will be unbiased as long as higher-order interactions are negligible.
3. Flexibility. OAME designs provide the opportunity to combine factors having differing numbers of levels in the same experiment. This is particularly useful when a study involves only qualitative or both qualitative and quantitative factors requiring differing numbers of levels.

Disadvantages

1. For a given design d , we say two effects are fully aliased (*see Aliasing in Fractional Designs*) or confounded if the **correlation** between their parameter estimates under model (1) (when their corresponding terms are included in the model) has absolute value 1 and we say two effects are partially aliased or confounded if the correlation between their estimates has absolute value between 0 and 1. The primary disadvantage with OAME designs, particularly those that are nearly saturated, is that many of the estimates for ME parameters will be fully or partially confounded with low order interactions. For example, in an

$\text{OAME}(18, 3^7 2^1)$ design d , because d is nearly saturated, there are at most two lower order interactions between MEs that can be estimated. Thus, most MEs in d will be at least partially aliased with some low order interactions. Whenever a design d has a number of MEs that are at least partially aliased with a number of low order interactions, we say that the design has a complex **aliasing** structure. A complex aliasing structure can sometimes lead to difficulty in the interpretation of a significant ME parameter estimate. For example, in the $\text{OAME}(18, 3^7 2^1)$ design d , if a parameter ME is found to be significant, then it may be difficult to determine (unless all two-factor and higher-order interactions are negligible) whether the significance was due to the associated factor effect or some combination of the partially aliased low order interactions. Hamada and Wu [4] have suggested a stepwise, regression-based procedure for analyzing data from designs having complex aliasing structures and their method of analysis can be useful when only a few effects are influential and the correlation between partially aliased effects is small to moderate. However, as also pointed out in Hamada and Wu [4], their technique is not foolproof. When the assumption of two-factor and higher-order interactions being negligible is valid, the OAME designs can be of great use in identifying influential factors in a screening process. However, when the assumption is not valid, it is possible to identify some factors which are not truly significant as being influential and completely fail to identify other factors which are truly influential.

Other OME Plans

As mentioned in the section titled “Orthogonal Array Main Effect (OAME) Designs”, OAME designs are special cases of OME plans. In fact, OAME designs provide one of the basic tools for constructing OME designs to handle experimental situations for which an OAME design may not exist. The simplest method for constructing OME designs from OAME plans is called the *method of collapsing factors*. We illustrate the technique through an example.

Example 2 Consider the OAME(9, 3⁴) design d which exists and has

$$X_d = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 2 & 2 & 2 \\ 1 & 3 & 3 & 3 \\ 2 & 1 & 2 & 3 \\ 2 & 2 & 3 & 1 \\ 2 & 3 & 1 & 2 \\ 3 & 1 & 3 & 2 \\ 3 & 2 & 1 & 3 \\ 3 & 3 & 2 & 1 \end{pmatrix} \quad (3)$$

Using d , we can now construct an OME(9, 3²2²) design $\tilde{d}$ using the method of “collapsing factors”. In particular, we assign all observations occurring at levels 1, 2, and 3 of factors 1 and 2 in d to the same levels for factors 1 and 2 in $\tilde{d}$. However, we also assign those observations occurring at level 1 of factors 3 and 4 in d to the same level of factors 3 and 4 in $\tilde{d}$ but assign those observations occurring at levels 2 and 3 of factors 3 and 4 in d to level 2 of factors 3 and 4 in $\tilde{d}$. Thus $\tilde{d}$ has

$$X_{\tilde{d}} = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 2 & 2 & 2 \\ 1 & 3 & 2 & 2 \\ 2 & 1 & 2 & 2 \\ 2 & 2 & 2 & 1 \\ 2 & 3 & 1 & 2 \\ 3 & 1 & 2 & 2 \\ 3 & 2 & 1 & 2 \\ 3 & 3 & 2 & 1 \end{pmatrix} \quad (4)$$

and we have “collapsed” factors 3 and 4 in d having three levels each to factors 3 and 4 in $\tilde{d}$ having two levels each. In doing so, we note that level 1 in factors 3 and 4 in $\tilde{d}$ occurs in three runs whereas level 2 of factors 3 and 4 in $\tilde{d}$ occurs in six runs. However, because the levels of each pair of factors in d occur equally often together, the property of proportional frequencies in d carries over to $\tilde{d}$ during the “collapsing” process. We also note that using the method of “collapsing factors”, additional OME designs can be constructed from d such as OME(9, 3³2¹), OME(9, 3¹2³), and OME(9, 2⁴).

Using the method of “collapsing factors”, a large number of OME designs can be constructed from OAME designs such as those listed in Table 1 or the web site mentioned in the section titled “Orthogonal Array Main Effect (OAME) Designs”. A collection of

useful OME designs can be found in Dey [5]. We also note that, as in the example above, when applying the method of “collapsing factors” to a given OAME design d , the property of proportional frequencies carries over from d to the OME design $\tilde{d}$ constructed.

Similar to OAME plans, the property of proportional frequencies makes it possible to find a lower bound for the number of observations required for an OME($N, s_1^{m_1} \dots s_k^{m_k}$) design. In particular, we have the following theorem which has been proved by Jacroux [6].

Theorem 2 Suppose that an OME design d requires $m \geq 3$ factors with factor i having s_i levels, $i = 1, \dots, m$ and assume $s_1 \geq s_2 \geq \dots \geq s_m$. If $N = \tilde{s}_1 \tilde{s}_2$ is the minimum possible value for integers $\tilde{s}_1$ and $\tilde{s}_2$ satisfying

1. $\tilde{s}_1 \geq s_2$ and $\tilde{s}_2 \geq s_2$;
2. $\tilde{s}_1 \tilde{s}_2 \leq 2s_1 s_2$;
3. $s_3 \times \{lcm(\tilde{s}_1, \tilde{s}_2)\} \leq \tilde{s}_1 \tilde{s}_2$,

where $lcm(x, y)$ denotes the least common multiple between positive integers x and y , then N is a lower bound for the number of observations required for d .

A design having N satisfying the conditions of Theorem 2 is called a *minimal OME plan*.

Comment If d requires m factors having level $s_1 \geq s_2 \geq \dots \geq s_m$, then another obvious lower bound for N is $\sum_{i=1}^m s_i - m + 1$ since this is the minimal number of runs required to estimate all MEs in d .

Example 3 Consider an experimental setting in which a screening experiment is to be run and requires the use of a design having two factors with three levels and two factors with two levels. Using Theorem 1, it is seen that a lower bound for the number of runs required for an OAME design is 36. On the other hand, it is seen using Theorem 2 that the lower bound for the number of observations required for an OME design is 9. We saw in Example 2 that an OME(9, 3²2²) exists which can be used to handle this experimental situation. Thus in this case, we see that the use of an OME design can provide substantial savings in terms of runs required over the best possible OAME design. Many other such situations can be found in which the use of OME designs provides similar savings in terms of runs required over corresponding OAME designs.

For a specific experimental situation requiring m

6 Main Effect Designs

factors with $\tilde{s}_1 \geq \dots \geq \tilde{s}_m$ levels, the following steps can be used to construct a specific OME design $\tilde{d}$ for use.

1. Use Theorem 2 to find a lower bound for the number of observations required for an OME plan to accommodate all m factors.
2. Consult a table of OAME designs such as given in Table 1 or at the website mentioned previously and find an OAME design d whose number of runs is equal to or as close as possible to the lower bound found in step 1 and having factors $i, i = 1, \dots, m$ with s_i levels, $s_i \geq \tilde{s}_i, i = 1, \dots, m$.
3. Collapse the levels of the factors $i = 1, \dots, m$ in d to the appropriate number of levels for factors $i = 1, \dots, m$ in $\tilde{d}$.

We illustrate the use of this procedure in the following example.

Example 4 Consider an experimental situation requiring three three-level factors and six two-level factors. What is the smallest $\text{OME}(N, 3^3 2^6)$ that can be run? Following the stepwise procedure outlined above, we proceed as follows:

1. Using Theorem 2, a lower bound for N is seen to be $N = 9$.
2. Consulting Table 1, we see that the smallest OA design d that has nine factors with three factors having at least three levels is $\text{OAME}(16, 4^3 2^6)$.
3. Using the method of collapsing factors, we can construct the desired $\text{OME}(16, 3^3 2^6)$ design $\tilde{d}$ by taking the three four-level factors in d and collapsing their levels so that we obtain the required three factors having three levels in $\tilde{d}$.

Once an OME has been selected for use, the actual analysis of data from the design would proceed, using regression and variable selection techniques. The systematic procedure of analysis suggested by Hamada and Wu [4] may also be of use under the same conditions mentioned in the previous section, but the limitations of the method should also be kept in mind.

As in the case of OAME designs, there are certain advantages and disadvantages an experimenter should keep in mind when using OME plans as screening designs.

Advantages over OAME designs

1. Economy of run size. Because OME designs are more general than OAME plans, it is often the case that the number of runs required to construct an OME design to handle a given number of factors having given numbers of factor levels is smaller than the number required to construct an OAME design. This is clearly illustrated in Example 3.
2. Because differences between factor level averages between different factors are orthogonal, this makes the estimation of ME parameters relatively easy in OME designs.

Disadvantages

1. Because most OME designs will be nearly saturated when used as screening experiments, many of the ME parameter estimates will be at least partially aliased with low order interactions which lead to a complex aliasing structure. All the problems mentioned earlier for complex aliasing structures in OAME designs hold true for OME plans as well.
2. When obtaining an OME design $\tilde{d}$ from an OAME design d through the method of “collapsing factors”, it will be the case that some of the factors in $\tilde{d}$ will have levels which occur in differing numbers of runs. Thus some ME parameters associated with these factors will be estimated with greater precision than others. This can result in a loss of efficiency. However, the loss of efficiency can be minimized by collapsing levels of a factor in d so that the levels of the resulting factor in $\tilde{d}$ occur as equally often in runs as possible.

Nonorthogonal ME Designs

In the previous sections, we introduced designs which allow for the orthogonal estimation of ME parameters associated with different factors. In this section, we consider designs which sometimes prove useful as screening designs, but which are nonorthogonal in the sense that ME parameters cannot necessarily be orthogonally estimated. In particular, we consider what we refer to as *nearly orthogonal array main effect (NOAME) designs*. NOAME designs were introduced by Wang and Wu [7]. In OAME designs, for any two factors i and j , each level of factor i occurs equally often with each level of factor j .

This latter property implies proportional frequencies between factors which ensure that ME parameters between different factors can be orthogonally estimated. The property of proportional frequencies between factors in both OAME designs and OME designs places some restrictions on the number of factors that can be accommodated in a given set of runs. For example, in a design requiring six runs and a $3^1 2^2$ fractional factorial experiment, it can be shown that neither an OAME design nor an OME design exists. However, by relaxing the condition of orthogonality between ME estimates for different parameters, Wang and Wu [7] give a method for constructing an NOAME design which can be used for such a situation.

Wang and Wu [7] give three different methods for constructing NOAME designs. In some cases, they use their methods to find designs which minimize the number of nonorthogonal pairs of columns of certain types and in other cases, they find designs which minimize the canonical correlations between two sets of effects. A list of parameters for the actual designs constructed by Wang and Wu [7] is given in Table 2, but for the actual construction of the designs given, the reader is referred to Wang and Wu [7].

Once again, the statistical analysis of NOAME designs usually relies upon regression analysis and variable selection techniques.

Advantages of NOAME designs over OME designs

1. Economy of run size. NOAME designs can be used to handle experimental situations where OAME and OME designs do not exist for a given number of runs, factors, and factor levels. Thus such designs are used in situations where other options do not exist.

Table 2 Nearly orthogonal array main effects designs

Number of observations	Design
6	$3^1 2^3$
10	$5^1 2^5$
12	$3^4 2^3, 6^1 2^5, 3^1 2^9, 3^5 2^1, 3^4 2^2$
15	$5^1 3^5$
18	$9^1 2^8, 3^4 2^8$
20	$5^1 2^{15}$
24	$8^1 3^8, 3^8 2^7, 4^1 3^8 2^4, 3^1 2^{21}, 6^1 2^{18}, 3^{11} 2^1$ $4^7 3^1, 4^1 3^9 2^1, 3^9 2^5, 4^6 3^1 2^3$
36	$4^{11} 3^1, 4^{10} 3^2$

Disadvantages

1. The analysis of NOAME designs is not as straightforward as that of orthogonal designs since parameter ME estimates between different factors are not necessarily orthogonal. The lack of orthogonality also leads to some loss of efficiency in terms of the estimating factor MEs.
2. The alias structure associated with NOAME designs tends to be even more complex than that of OAME and OME designs. Hence, all of the issues mentioned previously, associated with complex alias structures, hold for NOAME designs.

Minimum Aberration

Introduction

Two-level **factorial** and **fractional factorial** designs are most widely used in experimental investigations. When m factors, each with two levels such as high (+1) and low (−1), are to be studied in an experiment, one may choose a full factorial design in which all possible 2^m level combinations of the factors are investigated. Such a level combination of the factors is often referred to as a *run* of the design. However, for a moderately large number of factors, a two-level full factorial design requires a large number of runs, which may be very time consuming, too expensive, and even redundant (see [1, p. 243]). Therefore, investigators often turn to a fractional factorial design, in which only a fraction of runs of a full factorial design are studied. In general, a 2^{m-p} fractional factorial design studies m factors with a 2^{-p} th fraction of 2^m runs of a full factorial design. A good fractional factorial design allows one to investigate many factors with relatively small run size, while still enabling one to estimate important effects. In order to select good fractional factorial designs for a given dimension (i.e., m and p), Box and Hunter [2] introduced the idea of design *resolution*. Fries and Hunter [3] further proposed a refined *minimum aberration* criterion to assess fractional factorial designs with the same resolution.

Minimum Aberration in Regular Designs

In this section we define regular two-level fractional factorial designs, describe how they alias certain effects and explain how the minimum aberration criterion can be helpful in selecting a good design. We illustrate the ideas by considering an experiment in which it is desired to study 7 factors in 32 ($= 2^{7-2}$) runs. Denote the seven factors by numbers 1, 2, 3, 4, 5, 6, 7, which correspond to seven columns with entries ± 1 in the design matrix. A 2^{7-2} fractional factorial design can be constructed by first writing down a basic design consisting of 32 runs associated with a full factorial design in five factors, say, 1, 2, 3, 4, 5. Then we associate the two additional factors 6 and 7 with appropriately chosen

interactions involving the factors 1, 2, 3, 4, 5. For example, we may obtain a design D_1 by associating factors 6 = 123 and 7 = 234, where the multiplication of letters is the element-wise multiplication of their corresponding columns. Hence, main effects 6 and 7 of design D_1 are aliased by its three-factor interactions 123 and 234, respectively. The assignment of factors 6 and 7 can be rewritten as $I = 1236$ and $I = 2347$, where I is a column of “+1”. One can find another relation among the factors as $I = 1236 \times 2347 = 1467$ using the fact that two same letters result in the identity column I . Altogether we have $I = 1236 = 2347 = 1467$, which forms the *defining relation* of the design. The elements 1236, 2347, and 1467 in the defining relation are referred to as *words*. The number of letters in a word is called the *length* of the word or *word length*. The words 1236 and 2347, used to define additional factors 6 and 7, are referred to as the *design generators*. In general, the design generators plus all the possible products of them constitute the complete defining relation of a design. Two-level fractional factorial designs 2^{m-p} constructed as above have the complete defining relation and are known as *regular fractional factorial designs* or *simply regular designs*.

In regular fractional factorial designs, some of the effects are completely entangled, or aliased, with one another. From the defining relation, it is straightforward to find the **aliasing** structures. For example, multiplying the above defining relation on both sides by 1 yields $1 = 236 = 467 = 12347$. That is, the **main effect** 1 is aliased with two three-factor interactions 236, 467 and a five-factor interaction 12347. Similarly, $12 = 36 = 2467 = 1347$. The **estimation** of the two-factor interaction 12 is actually the sum of effects $12 + 36 + 246 + 1347$. In the literature, when an effect A is aliased with another effect B , it is also said that the effect A is confounded with the effect B , which means these two effects are indistinguishable from each other. Design D_1 can estimate all main effects, but cannot estimate some two-factor interactions such as 12 and 36, even if we assume that the three-factor and higher-order interactions are negligible. However, all two-factor interactions involving 5 in D_1 are estimable. Therefore, the aliasing structure is an important information in planning industrial experiments.

Let $A_i(D)$ be the number of words of length i in the defining relation of a design D . The *word length*

pattern is then the vector $W(D) = [A_1(D), A_2(D), A_3(D), \dots]$. Since any two columns of a two-level fractional factorial design are orthogonal, the minimum length of a word will be 3; the maximum length possible is the total number of factors in the design. Thus, the word length pattern of design D_1 above can be shortened to $W(D_1) = [A_3(D_1), A_4(D_1), A_5(D_1), A_6(D_1), A_7(D_1)] = [0, 3, 0, 0, 0]$.

Box and Hunter [2] introduced *resolution* as a criterion for selecting regular fractional factorial designs. The resolution R of a regular fractional factorial design is defined as the length of the shortest word in the defining relation of the design. Therefore, if a regular fractional factorial design is of resolution R , then no k -factor interaction is aliased with any other interaction containing less than $R - k$ factors. The resolution of a regular design is denoted by a Roman numeral subscript. For instance, the design D_1 mentioned above is of resolution IV and is denoted as 2_{IV}^{7-2} . The **design resolution** is a criterion to measure the occurrences of worst aliases of a regular fractional factorial design. In general, a design with a higher resolution is better. However, there may be many regular fractional factorial designs with the same resolution, especially for larger designs with many factors. Resolution alone is sometimes not sufficient to distinguish among regular fractional factorial designs. Suppose a design D_2 is obtained by redefining factors 6 and 7 in design D_1 above as $6 = 1234$ and $7 = 1245$. So design D_2 has the defining relation $I = 12346 = 12457 = 3567$. Both designs D_1 and D_2 are of resolution IV, but they have rather different alias structures. If we assume that interactions involving three or more factors are negligible, which is often the case at the initial stage of the investigation, design D_2 has only three pairs of aliases (i.e., $35 = 67$, $36 = 57$, and $37 = 56$) with respect to the two-factor interactions, whereas there are nine pairs of such aliases in design D_1 . Clearly, design D_2 is a better choice for a 2_{IV}^{7-2} , if there is little knowledge about the factors.

In order to discriminate among regular fractional factorial designs with the same resolution, Fries and Hunter [3] proposed the *minimum aberration* criterion based on the word length pattern. Suppose for any two regular fractional factorial designs D and D' , r is the smallest positive integer such that $A_r(D) \neq A_r(D')$. Then design D is said to have less aberration than design D' if $A_r(D) <$

$A_r(D')$. If there exists no other regular design having less aberration than design D , then D is said to be a minimum aberration design. Minimum aberration is a criterion to compare the frequency of aliases of regular designs at different levels sequentially, and a regular design having the smallest frequency of worst aliases is the best. For example, the word length pattern for design D_2 is $W(D_2) = [A_3(D_2), A_4(D_2), A_5(D_2), A_6(D_2), A_7(D_2)] = [0, 1, 2, 0, 0]$. Since $A_3(D_1) = A_3(D_2) = 0$ and $A_4(D_2) = 1 < 3 = A_4(D_1)$, design D_2 has less aberration than design D_1 . It is easy to check that design D_1 is a minimum aberration design. Chen *et al.* [4] and Wu and Hamada [5, Chapter 4, Appendix] listed minimum aberration (and other selected) two-level regular fractional factorial designs from 8 to 128 runs. Some important contributions related to minimum aberration can be found in Franklin [6], Chen and Wu [7], Chen [8], Tang and Wu [9], Chen and Hedayat [10], Suen *et al.* [11], and Cheng *et al.* [12]. There are many additional works on minimum aberration designs; see of Wu and Hamada [5, Chapter 4, References] for details.

Nonregular Designs and Generalized Minimum Aberration

Nonregular fractional factorial designs, or simply nonregular designs, are commonly obtained from Plackett–Burman designs given in Plackett and Burman [13] or more generally from Hadamard matrices by selecting a subset of the columns. Recall that a Hadamard matrix of order n is an $n \times n$ matrix with the elements ± 1 whose columns (and rows) are orthogonal to each other. The order n is a multiple of 4. Other widely used nonregular designs are selected from orthogonal arrays. See Hedayat *et al.* [14] and Wu and Hamada [5] for further details. While regular designs have a clear defining relation and therefore simple aliasing structures, the gap of runs for regular factorial designs is becoming larger and larger (4, 8, 16, 32, 64, 128, ...). In contrast, nonregular designs have no clear defining relation and thus their aliasing structures are very complicated, but they have a very flexible run size of a multiple of 4. Hamada and Wu [15] argued that the nature of the complex aliasing structure of nonregular designs could be exploited to estimate some interactions without increasing the number of runs. They proposed an

analysis strategy to turn the liability of the complex aliasing structure into the virtue of model estimability. Therefore, good nonregular designs not only provide a much wider range of possible experiment sizes but may also have advantages in the estimation of interactions; see the illustrative example in Wang and Wu [16].

The popular minimum aberration criterion was first proposed for selecting regular designs, and it cannot be directly applied to nonregular designs. In order to assess nonregular designs, one needs to find a suitable criterion. There are several significant articles in this direction as reported by Lin and Draper [17], Wang and Wu [16], and Box and Tyssedal [18]. The criteria proposed were reasonable and heuristic. Most of them however, were highly model based. They had no apparent connection with the minimum aberration criterion or no rigorous theoretical justifications. Deng and Tang [19, 20] proposed *generalized resolution* and *generalized minimum aberration* (GMA) for ranking nonregular two-level designs in a systematic approach. These criteria are based on a generalization of the word length pattern and is useful for comparing regular/nonregular designs. We give a more detailed description next.

Let D be a two-level (regular or nonregular) factorial design with n runs and m factors. The design D can also be regarded as a set of m column vectors of length n . For any subset with k columns selected from D , say, $s = \{\mathbf{x}_1, \dots, \mathbf{x}_k\}$, define $J_k(s) = |\sum_{i=1}^n x_{i1}, \dots, x_{ik}|$, where x_{ij} is the i th component of column vector $\mathbf{x}_j$. $J_k(s)$ is the absolute value of the sum of the interaction column $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k$.

For regular designs, $J_k(s)$ equals either 0 or n . When $J_k(s) = n$, it corresponds to a full confounding among these columns whose indices are in s . For nonregular designs, $J_k(s)$ can take values between 0 and n which means a partial confounding. For a design D , let r be the smallest integer such that $\max_{|s|=r} J_r(s) > 0$, where the maximization is over all the subsets of r distinct columns of D . Then the *generalized resolution* of D , proposed in Deng and Tang [19], is defined as $R(D) = r + [1 - \max_{|s|=r} J_r(s)/n]$. Obviously, $r \leq R(D) < r + 1$. For a regular design, $R(D) = r$ since $J_k(s)$ takes either 0 or n . Therefore, $\max_{|s|=r} J_r(s) > 0$ is equivalent to $\max_{|s|=r} J_r(s) = n$ for a regular design.

For nonregular designs, it is important to know the possible values of $J_k(s)$. It is straightforward to

see that $J_k(s)$ is a multiple of 4. Deng and Tang [20] derived a general formula for possible values of $J_k(s)$ and proved that the gap between two consecutive possible J values is a multiple of 8. We then list all possible values of $J_k(s)$ in decreasing order and denote the frequency distribution of $J_k(s)$ for all possible s out of k columns in D by $[f_{k1}, f_{k2}, \dots, f_{kg+1}]$, where f_{kj} is the frequency of $J_k(s)$ taking the j th largest possible value and $g = \lfloor \frac{n}{8} \rfloor$, the integer part of $\frac{n}{8}$. The total number of k -column subdesigns (*projections*) from an m -column design is a fixed number $\binom{m}{k}$ which is equal to $\sum_{j=1}^{g+1} f_{kj}$. Therefore, it is sufficient to consider the first g entries and let

$$F_k(D) = [f_{k1}, f_{k2}, \dots, f_{kg}] \quad (1)$$

The confounding frequency vector (or generalized word length pattern) of D , proposed by Deng and Tang [19, 20], is given by

$$W(D) = [F_3(D), F_4(D), \dots, F_m(D)] \quad (2)$$

Since only designs with orthogonal columns are considered, $F_1(D) = F_2(D) = 0$.

Note that for a regular design, f_{k1} is the number of words with length k and $f_{ki} = 0$ ($i > 1$) because $J_k(s)$ takes either 0 or n . Therefore, the corresponding confounding frequency vector reduces to the word length pattern for regular designs.

Any two fractional factorial designs D_1 and D_2 with the same run size and number of factors can be ranked by comparing their confounding frequency vectors element by element. Specifically, suppose r is the smallest integer such that $F_r(D_1) \neq F_r(D_2)$. Design D_1 is said to have less generalized aberration than design D_2 if $F_r(D_1) < F_r(D_2)$, which are compared element by element from the first entry to the last. In other words, we would sequentially compare the frequency of the components and prefer the one that minimizes the frequency of the largest value. As proposed first by Deng and Tang [19], a design is said to have *generalized minimum aberration* (also referred to as *minimum G aberration*) if there exists no other design having less generalized aberration. Clearly this criterion reduces to the traditional minimum aberration for regular designs. The GMA criterion can compare and assess any two factorial designs, whether or not they are regular.

Using the confounding frequency vector, one can rank various nonregular designs of m columns and n runs. Deng *et al.* [21] and Deng and Tang

[20] tabulated and ranked a collection of nonregular designs of run sizes 16, 20, and 24.

Other Related Criteria

Instead of counting the frequency of $J_k(s)$ in the confounding frequency vector $W(D)$, Tang and Deng [22] considered a relaxed version as $B_k(D) = n^{-2} \sum_{|s|=k} [J_k(s)]^2$ and proposed *minimum G_2 aberration* which is based on the vector $W_B(D) = [B_3(D), B_4(D), \dots, B_m(D)]$. They further developed a complementary design theory for the minimum G_2 aberration criterion. Cheng *et al.* [23] demonstrated that the criterion based on $W_B(D)$ is consistent with some model-dependent efficiency criteria under certain two-factor interaction models. Cheng and Tang [24] further developed a general theory of minimum aberration based on some statistical principles and their theory provided a unified framework for minimum aberration.

While the work on GMA shows a promising direction in the study of nonregular designs, this approach is mostly suitable for two-level designs. By studying treatment contrasts and ANOVA models, Xu and Wu [25] proposed a generalization of the minimum aberration criterion that can be used for multilevel designs. To develop an additional theory for the proposed criterion, they successfully explored the connection between the theory of factorial designs and the theory of coding. In other words, instead of studying the relationship between the factors (columns), one can investigate the relationship between the runs (rows). Following this approach, Xu [26] proposed the *minimum moment aberration* criterion, which is based on the power moments, for measuring the similarity among runs (rows). Minimizing the power moments makes runs as dissimilar as possible. Therefore, good designs should have small power moments.

Using power moments of the projection designs and counting their frequency distributions, Xu and Deng [27] proposed the *moment aberration projection* criterion to rank and classify nonregular designs (including multilevel designs). Two fractional factorial designs are *isomorphic* if one can be obtained from the other by permuting rows and columns and/or changing the signs of columns. In general, it is time consuming to perform an isomorphism check between two designs as demonstrated in Chen

et al. [4]. The confounding frequency vector and the moment aberration projection, although originally proposed to rank and assess designs, are also useful in testing for isomorphism. Clearly, two designs with different confounding frequency vectors or moment aberration projections are not isomorphic. On the other hand, two nonisomorphic designs may have the same confounding frequency vector or moment aberration projection. Xu and Deng [27] demonstrated that moment aberration projection has a better classification power than the confounding frequency vector. The ranking of various designs given by both criteria are fairly consistent, but not identical, with each other.

Fang and Mukerjee [28] found a connection analytically between the minimum aberration criterion and a uniformity criterion in the area of **uniform design**. See Fang *et al.* [29, Chapter 3] for more references.

Optimal Design

Introduction

With luck, and perhaps after data transformation, the analysis of a well-designed experiment may require little more than a few simple plots that reveal how the responses depend on the factors. Subsequent **estimation** of the parameters modeling this dependence usually requires the use of **least squares**. In a good experiment the variances and covariances of the estimated parameters will be small. Optimal experimental designs minimize functions of these variances and so provide good estimates of the parameters.

This article is mainly concerned with D-optimality in which the generalized variance of the parameter estimates is minimized. Many of the standard designs, such as the 2^m factorials and the series of 2^{m-f} fractional factorials, as well as standard designs for **mixture experiments** and some designs for second-order response surfaces can be justified because they are D-optimal, in addition to other justifications. However, a major feature of the methods of optimal experimental design is the ability to find good designs in nonstandard situations. Here are some advantages of the approach:

1. the availability of algorithms for the construction of designs;
2. the calculation of good designs for a specified number of trials;
3. the provision of simple, but incisive, methods for the comparison of designs;
4. the ability to divide response-surface and other designs into blocks of a specified size;
5. the determination of good response-surface designs over nonregular regions;
6. the construction of designs for mixture models, perhaps over nonregular regions;
7. the ability to find designs for nonstandard models, such as nonlinear models.

The first six of these seven points are illustrated in the sections that follow. Chapter 17 of Atkinson *et al.* [1] gives a thorough coverage of optimal designs for nonlinear models.

The article starts in the section titled “Simple Regression” with linear and quadratic regression in one variable. Several criteria of optimality are

introduced in the third section. Examples of numerically constructed D-optimal designs are given in the section titled “Second-Order **Response Surface** in Two Factors”. These include designs for an arbitrary number of trials, blocked response-surface designs and designs over nonregular design regions. The distinction between exact and continuous designs is made in the following section in “Exact and Continuous Designs” and used in the section titled “The General Equivalence Theorem and Design Efficiency” in the description of the general equivalence theorem for D- and G-optimal designs. The theorem is also used to demonstrate the optimality of designs and calculate efficiencies. Algorithms for design construction are in the section titled “Design Algorithms”. Extensions, including designs for detecting **lack of fit**, and references to the literature on optimal experimental design are in the section titled “Discussion and Literature”.

Simple Regression

Since optimal designs focus on the variances of the estimated parameters, we need to specify a model. We start with the simplest interesting case, linear regression in one variable, which serves to introduce some important ideas. There is a single response y , the expected value of which depends linearly on the value of the factor or process variable x through the relationship

$$E(y) = \beta_0 + \beta_1 x \quad (1)$$

The design problem is to choose N values of x at which measurements are to be taken. Although there are N observations, the number of distinct values of x used in the experiment, which we call n , may be much less than N . These n values of x must lie in the experimental region $\mathcal{X}$. For a single variable we can scale the values of x such that $-1 \leq x \leq 1$, where ± 1 correspond to the minimum and maximum values of the variable, which might typically be time, temperature, pressure, stirring speed, or catalyst concentration.

The model is to be fitted to the data by least squares. For this method to be appropriate, the variance of the observations should be constant and we write $\text{var}(y) = \sigma^2$. The least-squares estimators of the parameters in equation (1) are called $\hat{\beta}_0$ and $\hat{\beta}_1$ with

$$\text{var}(\hat{\beta}_1) = \frac{\sigma^2}{\sum (x_i - \bar{x})^2} \quad (2)$$

2 Optimal Design

where the sample average $\bar{x} = \sum x_i / N$. Here and in equation (2) the summations are over all N values x_i . From equation (2) the variance of $\hat{\beta}_1$ is minimized when $\sum (x_i - \bar{x})^2$ is maximized. For a fixed number of trials N this occurs when all trials are at $+1$ or -1 . If N is even, exactly half the trials will be at $x = +1$ and the other half at $x = -1$. This design has $\bar{x} = 0$, so that $\text{var}(\hat{\beta}_0) = \sigma^2 / N$ which does not depend any further on the design. This design is therefore optimal for both parameters.

This design has many of the features of an optimal design. The number of support points of the design n , here two, may be appreciably less than the number of trials N . The fine structure of the design depends on the values of N , here whether it is even or odd, in which case one more trial is put at one end of the design region; it does not matter which. A third feature is that the design covers the whole of the design region, using the most extreme values of x available. In any application of the design, the order in which the two treatments $x = -1$ and $x = 1$ are applied should be randomized (*see Randomization in Experimental Designs*), to avoid any confounding with omitted variables. For example, if experiments are performed over time, gradual fouling of catalysts may mean that yields slowly decline during the experiment. If all trials at one level of x were performed in the second half of the experiment, the decline in yield would be confounded with any effect of the factor. Joiner [2] gives further examples of such “lurking variables”.

Fitted models are often used for prediction. The prediction at the point x , not necessarily included in the data from which the parameters were estimated, is

$$\hat{y}(x) = \hat{\beta}_0 + \hat{\beta}_1 x = \bar{y} + \hat{\beta}_1 (x - \bar{x}) \quad (3)$$

with variance

$$\text{var}\{\hat{y}(x)\} = \sigma^2 \left\{ \frac{1}{N} + \frac{(x - \bar{x})^2}{\sum (x_i - \bar{x})^2} \right\} \quad (4)$$

The optimal design found in this section for parameter estimation also has a minimax property for prediction: it minimizes the maximum variance of the prediction $\hat{y}(x)$ over $\mathcal{X}$. We discuss design for prediction further in the section titled “Criteria of Optimality”.

Optimal designs are tailored to the model that is assumed; particularly when there is one factor, the

designs often have the same number of design points as there are parameters. An example is the design at two points for the two-parameter regression model. An objection to such a design is that it does not provide for checking the model, for which trials at three or more values of x are needed. This suggests that the design should also be efficient in case the relationship is a second-order model

$$E(y) = \beta_0 + \beta_1 x + \beta_2 x^2 \quad (5)$$

It is always possible that an even-higher-order model is required, but empirical evidence from the results of decades of experimentation has shown that third- or higher-order models are rarely needed. If such models seem to be required, data transformations, such as the power transformations analyzed by **Box** and Cox [3], are often called for.

Polynomial models such as equations (1) and (5) can often be thought of as Taylor series approximations of some underlying more complicated model. In such cases, relatively simple polynomial models may provide good predictions of the response, the **bias** of the approximation being offset by a low variance due to a model with few estimated parameters. The trade-off between bias and variance and its effect on the design of experiments is one of the central topics of response-surface methodology (*see Response Surface Methodology*).

The design for the three-parameter second-order model, equation (5), introduces further aspects of the dependence of the optimal design on the precise purpose of experimentation. Unlike the two-point design for the first-order model, there is now no overall optimal design for all parameters. Testing whether the first-order model is adequate is equivalent to testing whether $\beta_2 = 0$. The variance of $\hat{\beta}_2$ is minimized by a design that puts half the trials at $x = 0$ and divides the remaining half between $x = -1$ and $x = 1$. But the design that provided the best estimates of all three parameters, in the sense of D-optimality described in the next section, puts one-third of the trials at each of these three points. In a satisfactory manner, the optimal design depends on the precise purpose of the experiment.

Criteria of Optimality

This section mainly describes the criterion of D-optimality which provides designs minimizing the generalized variance of the estimated parameters.

We consider a general experiment in which there are m factors and write the linear model as

$$E(y) = F\beta \quad (6)$$

Here y is the $N \times 1$ vector of responses, β is a vector of p unknown parameters, and F is the $N \times p$ extended design matrix. The i th row of F is $f^T(x_i)$, a known function of the m explanatory variables. For the quadratic model equation (5), for which $m = 1$ and $p = 3$,

$$f^T(x_i) = (1 \quad x_i \quad x_i^2) \quad (7)$$

The design is determined by the experimental values of x . The extended design matrix reflects not only the design but in addition the model to be fitted.

We assumed in the section titled ‘‘Simple Regression’’ that the observational errors were independent with constant variance σ^2 . This value usually does not depend on the design. However, failure to block the experiment (*see Blocking*), when there are block effects, can lead to an increase in the estimate of σ^2 and a loss of power of tests about parameter values.

The least-squares estimator of the parameters is

$$\hat{\beta} = (F^T F)^{-1} F^T y \quad (8)$$

where the $p \times p$ matrix $F^T F$ is the information matrix for β . The larger $F^T F$, the greater is the information in the experiment.

With σ^2 constant, the **covariance** matrix of the least-squares estimator is

$$\text{var } \hat{\beta} = \sigma^2 (F^T F)^{-1} \quad (9)$$

The variance of $\hat{\beta}_j$ is proportional to the j th diagonal element of $(F^T F)^{-1}$ with the covariance of $\hat{\beta}_j$ and $\hat{\beta}_k$ proportional to the (j, k) th off-diagonal element. If we are interested in the comparison of experimental designs, the value of σ^2 is not relevant, since the value is the same for all proposed designs for a particular experiment.

Confidence regions for all p elements of β are of the form

$$(\beta - \hat{\beta})^T F^T F (\beta - \hat{\beta}) \leq k \quad (10)$$

In the p -dimensional space of the parameters, equation (10) defines an ellipsoid, the boundary of which is a contour of constant residual **sum of squares**.

The volume of the ellipsoid is inversely proportional to the square root of the determinant $|F^T F|$. From the expression for $\text{var } \hat{\beta}$ in equation (9), $\sigma^2 |(F^T F)^{-1}| = \sigma^2 / |F^T F|$ is called the *generalized variance of $\hat{\beta}$* . Designs which maximize $|F^T F|$ minimize this generalized variance and are called *D-optimal* (for Determinant).

Interest in the fitted model may be not only in the parameters, but also in the quality of the predictions. The predicted value of the response for simple regression is given by equation (3). For the general model with p parameters, equation (6), the prediction can be written

$$\hat{y}(x) = \hat{\beta}^T f(x) \quad (11)$$

with variance

$$\text{var}\{\hat{y}(x)\} = \sigma^2 f^T(x) (F^T F)^{-1} f(x) \quad (12)$$

Designs which minimize the maximum over $\mathcal{X}$ of $\text{var } \hat{y}(x)$ are called *G-optimal*. As the theorem of the section titled ‘‘The General Equivalence Theorem and Design Efficiency’’ indicates, as N increases, D-optimality and G-optimality give increasingly similar designs.

An alternative to this minimax approach to $\text{var } \hat{y}(x)$ is to find designs that minimize the average value of the variance over $\mathcal{X}$. Such designs are variously called *I-optimal* or *V-optimal* from Integrated and Variance. Another criterion of importance in applications, particularly for nonlinear models, is that of *c-optimality* in which the variance of the linear combination $c^T \hat{\beta}$ is minimized, where c is a $p \times 1$ vector of constants. We do not exhibit such designs in this article, but focus on D- and G-optimality. Details of these and other design criteria are in Chapter 10 of Atkinson *et al.* [1].

Second-Order Response Surface in Two Factors

Many standard designs which have been derived over the years by a variety of methods share the property that they are D- and G-optimal. One example is the series of 2^m factorial designs (*see Factorial Experiments*) and their symmetric fractions forming the 2^{m-f} fractional factorial designs (*see Fractional Factorial Designs*), which can also be used to construct D-optimally blocked 2^m designs. Some

Figure 1 Second-order response surface in two factors: D-optimal designs for number of trials $N = 9$ and 13; heavy dots indicate support points with two observations

properties of the designs are discussed as Example 6. But these excellent properties do depend on the number of trials N . If this is not a power of 2 then only some of the 2^m points of the full factorial will be selected as design points or to be replicated, depending on whether N is less than or greater than 2^m ; the methods of optimal design construction will then be needed to determine these points. Similarly, the designs depend on the design region $\mathcal{X}$. If not all 2^m combinations of the high and low (+1 and -1) values of the factors are available, designs will need to be calculated over this irregular region. This section presents examples of the construction of designs for arbitrary N , for nonregular design regions and also for **blocking**. In the case of the blocked 2^m factorial, we might be forced by, for example, the size of batches of raw materials, to have blocks which are not all of size 2^{m-f} .

We now use the second-order polynomial in two factors to demonstrate some of the properties of D-optimal designs and of the versatility of the approach based on the theory of design optimality. The model is

$$E(y) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{11} x_1^2 + \beta_{22} x_2^2 + \beta_{12} x_1 x_2 \quad (13)$$

Although optimal designs depend on the model, the designs we find also have high efficiency for models in which some of the terms in equation (13) are absent.

Initially we take $\mathcal{X}$ as the square region $[-1, 1]^2$. Numerical searches for the design maximizing $|F^T F|$ will be confined to a grid of N_C candidate points, rather than to searches over the continuous region. Very little is lost in terms of the value of $|F^T F|$, the maximization is simplified and a grid of values corresponds to much experimental practice where settings are rounded to convenient values, such as 5°C intervals of temperature. The algorithms used to find the designs are outlined in the section titled “Design Algorithms”.

Example 1: Dependence of D-Optimal Design on N When $N = 9$ the D-optimal design maximizing $|F^T F|$ is the 3^2 factorial with trials at all combinations of the values -1, 0, and 1 for x_1 and x_2 . This design is plotted in Figure 1(a). For $N = 13$, the 3^2 design is augmented by the 2^2 factorial at ± 1 , that is by replicating the corner points of the 3^2 factorial, as shown in Figure 1(b). This is distinct from the conventional central composite design (see **Central Composite Designs**) in which the center point, that is the point $x_1 = x_2 = 0$ is replicated (see **Center Points**). In either design the replicated observations can be used to provide a model free estimate of the error variance.

For this second-order model, p , the number of parameters is six, which is therefore the minimum value of N . The D-optimal design for $N = 6$ has three design points that belong to the 3^2 factorial and

Figure 2 Second-order response surface in two factors. Optimal design for blocks of 6 and 7 trials, a total of $N = 13$ trials

three that do not. This design is only slightly better than the best design supported at six points of the 3^2 . As N increases, the number of points of the optimal design that are not factorial points decreases and the efficiency of fractions of the factorial increases. Some details, together with the definition of design efficiency, are in the section titled “The General Equivalence Theorem and Design Efficiency”.

Example 2: Blocking We now find designs for the second-order model (13) in which the trials are divided into two blocks of predetermined size. We assume additive blocking, so the model in equation (13) is augmented by an indicator variable for blocks at two levels. As an example, Figure 2 shows the division of 13 trials into two blocks, one of size 6 and the other of size 7.

This design is one of several with the same value of $|F^T F|$, including some designs from searching over the points of the 5^2 factorial in which the 3^2 factorial is augmented by points with at least one coordinate at ± 0.5 . The design of Figure 2 is symmetrical in x_1 and x_2 . But, in general, the labeling of the variables can be interchanged, as can the order of the blocks. This design has the advantage that its projection is the design for $N = 13$ in Figure 1(b). Thus the design is D-optimal whether or not blocking is required.

Example 3: Nonregular Design Region We consider a nonregular design region in which some

extreme values of x_1 and x_2 are excluded; in a chemical process these might correspond to conditions so severe that the product is degraded, or so dilute or cold that the desired reactions do not occur at a significant rate. Such a design region is shown in Figure 3. Optimal designs were found by searching over the 63 points of the 11^2 factorial that are included in the design region.

Figure 3 gives designs for $N = 9$ and 13. Although there are some other designs that are not far from these designs in efficiency, it is hard to summon up any intuition that leads to efficient designs; the algorithmic methods of optimal experimental design seem essential for the construction of efficient designs.

Finally, Figure 4 shows the D-optimal design when the 13 trials are divided into two blocks of sizes 4 and 9. In this case the projection of the two designs does not quite give the optimal unblocked design for $N = 13$ in Figure 3.

Example 4: Mixture Experiments In mixture experiments (*see Mixture Experiments*) the response depends on the proportion of the various components, but not on their amount. This imposes constraints on the values of the m factors and the resulting experimental region is a simplex in $m - 1$ dimensions.

The statistical study of mixture experiments was introduced by Scheffé [4]. Cornell [5] gives a book-length treatment. Because of the constraints on the

Figure 3 Second-order response surface in two factors with a nonregular design region: D-optimal designs for number of trials $N = 9$ and 13; heavy dots indicate support points with two observations

factors, not all terms in standard polynomial models are estimable. However, optimal design methods provide D-optimal designs for Scheffé's linear models. Chapter 16 of Atkinson *et al.* [1] gives the details of the designs, including blocked designs similar to those of Figure 4.

It is often necessary to introduce further constraints on the values of the factors to ensure that all mixtures in the experimental region are of interest; Martin *et al.* [6] give examples in glass manufacture. The resulting design regions can be hard to

visualize. However, once the design region has been given a mathematical description, optimal designs can readily be found by methods similar to those illustrated above for experiments involving response-surface models.

Exact and Continuous Designs

The D-optimal designs found so far have been for a specified model, design region $\mathcal{X}$ and number of trials N . As Figures 1 and 3 show, the structure of the

Figure 4 Second-order response surface in two factors with a nonregular design region: D-optimal design for blocks of 4 and 9 trials, a total of $N = 13$ trials; heavy dots indicate support points with two observations

designs can depend on the value of N . However, as N increases, the dependence decreases and the series of *exact* designs for specific values of N tends to a limiting *continuous* design independent of N . This section describes some uses of continuous optimal designs: they are often easier to find than an exact design for one specific N and they can readily be approximated to provide good exact designs for many values of N . The next section shows how continuous designs can be checked for optimality. Implications for algorithms for finding exact designs are given in the section titled “Design Algorithms”.

The theory was introduced in Kiefer [7] and developed in a series of further papers. Kiefer’s work on optimal design is collected in Brown *et al.* [8]. A basic idea is to write designs as probability measures.

Suppose an exact design has n points of support with r_i the integer number of trials at experimental conditions x_i . This design can be written as

$$\xi_N = \left\{ \begin{array}{cccc} x_1 & x_2 & \dots & x_n \\ r_1/N & r_2/N & \dots & r_n/N \end{array} \right\} \quad (14)$$

where $\sum r_i = N$. The measure ξ_N specifies the experimental conditions and the proportion of experimental effort at each condition. For example, for a response-surface design in m factors, the vector x_i gives the values of all m factors for the r_i replicate observations at the i th set of conditions; often for an exact design r_i will be 1.

The information matrix introduced in equation (8) can be written in terms of this measure as

$$F^T F = N M(\xi_N) \quad (15)$$

Likewise, the variance of the predicted response, introduced in equation (12), can be written in the standardized form

$$d(x, \xi_N) = \frac{N \text{var}\{\hat{y}(x)\}}{\sigma^2} = f^T(x) M^{-1}(\xi_N) f(x) \quad (16)$$

The continuous design ξ is found by replacing the fractions r_i/N in ξ_N by weights w_i . At the end of the section titled “Simple Regression” it was stated that the D-optimal continuous design for the quadratic model in one variable with $\mathcal{X} = [-1, 1]$ was

$$\xi^* = \left\{ \begin{array}{ccc} -1 & 0 & 1 \\ 1/3 & 1/3 & 1/3 \end{array} \right\} \quad (17)$$

where ξ^* , rather than ξ , indicates optimality. This design puts one-third of the trials at each of the three levels of x ; $-1, 0$, and 1 . For any N that is a multiple of three we can find the exact optimal design by putting $N/3$ trials at each of these sets of experimental conditions. For other values of N a good design is to distribute the trials as evenly as possible over these three points.

The General Equivalence Theorem and Design Efficiency

Exact D-optimal designs such as those of the section titled “Second-Order Response Surface in Two Factors”, maximize $|F^T F|$. From equation (15) D-optimal continuous designs therefore maximize $|M(\xi)|$. Kiefer and Wolfowitz [9] provide an equivalence theorem relating D- and G-optimal designs that provides a method of checking the optimality of any continuous design.

If ξ^* is a D-optimal design measure, then ξ^* also minimizes the maximum over $\mathcal{X}$ of the standardized variance of prediction $d(x, \xi)$ given by equation (16); that is ξ^* is also G-optimal. If we write this maximum as

$$\bar{d}(\xi) = \max_{x \in \mathcal{X}} d(x, \xi) \quad (18)$$

then $\bar{d}(\xi^*) = p$, the number of parameters of the linear model. For any nonoptimal design ξ the maximum over $\mathcal{X}$ of $d(x, \xi)$ is greater than p , which provides a method for checking for D-optimality.

The theorem holds for continuous optimal designs. Exact optimal designs such as that of equation (16) for the quadratic model when N is a multiple of 3 will clearly also satisfy it. But, for example, the exact D-optimal design when $N = 9$ of Figure 1 will not satisfy the theorem.

The equivalence theorem provides a **benchmark** for the comparison of designs. To compare a continuous design ξ with the optimal design ξ^* we define the D-efficiency as

$$D_{\text{eff}} = \left\{ \frac{|M(\xi)|}{|M(\xi^*)|} \right\}^{1/p} \quad (19)$$

The comparison of information matrices for designs that are measures removes the effect of the number of observations. Taking the p th root of the ratio of the determinants in equation (19) results in an

efficiency measure which has the dimensions of a variance, irrespective of the dimension of the model. Since the variance of estimated regression coefficients is inversely proportional to the number of observations, two replicates of a design measure for which $D_{\text{eff}} = 50\%$ would be as efficient as one replicate of the optimal measure.

Example 5: Quadratic Model in One Variable

The D-optimal continuous design for the quadratic model in one variable with $\mathcal{X} = [-1, 1]$ is given in equation (16). The claim that this design is D-optimal can be checked using the general equivalence theorem through calculation of the variance of the predicted response.

For this design $d(x, \xi^*)$ is the quartic given by

$$d(x, \xi^*) = 3 - \frac{9x^2}{2} + \frac{9x^4}{2} \quad (20)$$

which has a maximum over $\mathcal{X}$ of 3 at $x = -1, 0$, or 1 , the three design points. Further, this maximum value is equal to the number of parameters p . The plot in Figure 5 exhibits the optimality of the design since the values of three at the design points are indeed the optima over $\mathcal{X}$.

Example 6: 2^m Factorial and Fractions The first-order model in m factors with main effects and all

Figure 5 Quadratic model in one variable; $d(x, \xi^*)$ over $\mathcal{X}$ for the design of equation (16) which puts equal weights at $x = -1, 0$, and 1 . Since the maximum value is three, which is the number of parameters in the model, the design is D-optimal

possible interactions may be written as

$$E(y) = \beta_0 + \sum_{i=1}^m \beta_i x_i + \sum_{i=1}^{m-1} \sum_{j=i+1}^m \beta_{ij} x_i x_j + \cdots + \beta_{ijk \dots} x_i x_j x_k \cdots \quad (21)$$

When $\mathcal{X}$ is cuboidal, the D-optimal continuous design is the equireplicated 2^m factorial, which has $n = 2^m$ points of support at all combinations of values of ± 1 for each factor. If the full model (21) is fitted $p = N$ and $M(\xi^*)$ is the identity matrix. Then $d(x, \xi^*) = p$ at the design points and the equivalence theorem for continuous D-optimality is satisfied. Because of the orthogonality of the design, reflected in the diagonal nature of $M(\xi^*)$, the same design is optimal if terms are omitted from equation (21) or if the design is projected by the omission of one or more factors. Provided all the terms in the model can be estimated, the regular fractions of the design, that is the series of 2^{m-f} fractional factorials, are also the continuous D-optimal designs.

It is clear when analyzing the properties of this design that the maximum values of $d(x, \xi^*)$ occur at the points $x_i = \pm 1$. However, with more complicated examples, it is prudent to search $\mathcal{X}$ more carefully. Suppose the design used was a shrunken 2^m factorial with $x_i = \pm c$, $c < 1$. Then $d(x, \xi)$ would again equal one at the points of support of the design. However, this would not be the optimal design, since these would not be the maximum values of $d(x, \xi)$ over $\mathcal{X}$.

Example 7: Second-Order Response Surface in m Factors The second-order polynomial in m factors is

$$E(y) = \beta_0 + \sum_{j=1}^m \beta_j x_j + \sum_{j=1}^{m-1} \sum_{k=j+1}^m \beta_{jk} x_j x_k + \sum_{j=1}^m \beta_{jj} x_j^2 \quad (22)$$

Farrell *et al.* [10] show that the D-optimal continuous design for a cuboidal experimental region is supported on subsets of the points of the 3^m factorial, with the members of each subset having the same number of nonzero coordinates. Only three subsets are required, over each of which a specified design weight is uniformly distributed. For $m \leq 5$ the subsets have support $\{[0], [m-1], [m]\}$, that is the

center point, the midpoints of edges, and the corner points of the 3^m factorial. For larger values of m , other subsets also support optimal designs. It is interesting to note that the central composite designs ([11]; see **Central Composite Designs**), which belong to the family ($[0]$, $[1]$, $[m]$), cannot provide the support for a D-optimal continuous design when $m > 2$.

The number of support points of these continuous D-optimal designs increases rapidly with m , being 113 for $m = 5$. Exact designs with drastically reduced support are therefore required. Since the D-optimal continuous designs have support on the points of the 3^m factorial, it is reasonable to expect that good exact designs for small N can be found by searching over the points of these factorials. Table 11.7 of Atkinson *et al.* [1] summarizes designs found by such searches.

The minimal design has $N = p$. For $2 \leq m \leq 5$, these design all have efficiencies above 85% but designs with appreciably higher efficiencies can be found at the cost of only a few more design points. For $m = 3$, when $p = 10$, one design with $N = 14$ has an efficiency of 97.59%. When $m = 4$, $p = 15$ and a design with $N = 18$ has an efficiency of 93.11%. Finally, for $m = 5$ and $p = 21$, the best design with $N = 26$ is 95.19% efficient. The addition of one or a few trials above $N = p$ causes an appreciable increase in the efficiency of the design, in addition to the reduced variance of parameter estimates coming from a larger design with larger N .

Section 11.5 of Atkinson *et al.* [1] tabulates both continuous and exact D-optimal response-surface designs including designs for spheroidal regions. Chapter 15 of the same book discusses the blocking of response-surface designs.

Example 8: Second-Order Response Surface in Two Factors The designs in Figure 1 for the two-factor response surface model when $N = 9$ and 13 illustrate the dependence of exact optimal designs on the value of N . The continuous D-optimal design, like these two designs, is supported on the points of the 3^2 factorial with weight 0.1458 at each corner point $(\pm 1, \pm 1)$, weight 0.0802 at each center points of the edges $(0, \pm 1; \pm 1, 0)$ and weight 0.0960 at the center point of the design. Relative to this continuous design the exact design for $N = 9$ has a D-efficiency of 97.40%, whereas the value for $N = 13$ is 99.77%.

The smallest design, the exact D-optimal design for $N = 6$, has three support points that are not those of the 3^2 factorial and a D-efficiency of 89.15% relative to the continuous optimal design. The best design on six points of the 3^2 factorial has a very slightly lower efficiency of 88.49%. The best designs of both types for $N = 7$ and 8 already have efficiencies close to, or above, 95%. The conclusion is that, even for these very small designs, fractions of the 3^2 factorial provide efficient designs, as they do for higher values of m in Example 7. Application of the methods of optimal experimental design allows us to quantify the loss involved in experimenting at only these three levels.

Design Algorithms

Algorithms for the construction of continuous designs can either use relatively straightforward function maximization or be based on the general equivalence theorem through the properties of the variance $d(x, \xi)$. These show that the optimal design contains only points with the highest possible value of $d(x, \xi)$, namely p .

In the sequential construction of continuous D-optimal designs, observations are added at the value of x in $\mathcal{X}$ for which this variance is a maximum; $\mathcal{X}$ can either be treated as a continuous region or discretized to give a set of N_C candidate points. For an N -trial design written as the measure ξ_N , let the measure $\bar{\xi}_N$ put unit mass at the point where this maximum occurs. Then, provided $\bar{d}(\xi) > p$, we take

$$\xi_{N+1} = \frac{(N\xi_N + \bar{\xi}_N)}{(N+1)} \quad (23)$$

If $\bar{d}(\xi) = p$, the equivalence theorem of the section titled “The General Equivalence Theorem and Design Efficiency” shows that the design is D-optimal and the algorithm stops.

Convergence is not monotonic. As an instance, starting from the nine-trial design of Figure 1 for the two-factor response-surface model, we find that the variance is maximum at the corners of the region and one trial would be added at one of these corners. Continuing the procedure with $N = 10$ would lead to the addition of a trial at another corner point, and so on, until the design for $N = 13$ is obtained when $\bar{d}(\xi_{13})$ is very close to p . Addition of one further trial must destroy the symmetry of this design and

there will be a slight decrease in D-efficiency and an increase in the value of $\bar{d}(\xi)$, with $\bar{d}(\xi_{14}) > \bar{d}(\xi_{13})$. However, continuing with the sequential addition of trials in this way will eventually lead to a design with the weights given in the first paragraph of Example 8.

The convergence of such algorithms can be slow, but ultimate convergence is usually not required. Starting from an arbitrary design, the algorithm typically adds mass at a restricted number of conditions in $\mathcal{X}$. These conditions suggest the support of the optimal design. Once this pattern becomes clear, either the arbitrary starting design can be rejected and the algorithm restarted or the information gained can be used to guide maximization of the function $|M(\xi)|$. The advantage of the sequential algorithm is that it reduces the search for an optimal design to a sequence of optimizations in m dimensions.

Exact designs for N trials are usually found using exchange algorithms. It now follows from the equivalence theorem that the n support points of the design should have high values of $d(x, \xi)$ and the $N_C - n$ unused candidate points should have low values. Exchange algorithms explore the replacement of one of the N trials of the design by any of the other $N_C - 1$ candidate points, thereby allowing for a possible increase in replication of points already in the design. In the original algorithm [12] all $(N_C - 1) \times n$ exchanges were considered and the one leading to the largest increase in $|M(\xi_N)|$ made. At this point n may change, although N is constant. The process was then repeated until no further improvement was found. More recent algorithms [13, 14] independently order the values of $d(x, \xi_N)$ for the candidate and support points and make the first exchanges in the ordered lists that increases $|M(\xi_N)|$. Again the process is repeated until no further improvement is found. Whatever algorithm is used, the search is repeated several times from random starting points.

Computer procedures for finding D-optimal designs of the kind given here, such as Example 3, accordingly require the ability to specify a model and a list of candidate points. Commercial packages with this flexibility include Design Expert, JMP, SAS, and WebDOE. The R package AlgDesign is downloadable from <http://cran.r-project.org> and the Gosset package of Hardin and Sloane [15] is at <http://www.research.att.com/~njas/gosset/>.

Discussion and Literature

The motivation for optimal designs in the introduction to this article was that they provide a means of minimizing functions of the variances of the estimated parameters. Box [16, Chapter 9] argues that it is doubtful if single criterion optimal designs are useful in locating designs satisfying the compromises between objectives required in a practical experiment. Although the focus of this article is on D-optimality, the theory and algorithms extend straightforwardly to compound designs in which a weighted combination of criteria can be employed to find a design that is, for example, simultaneously good for parameter estimation, establishing a response transformation, and for prediction in a specified region. A general approach to compound designs is given in Chapter 21 of Atkinson *et al.* [1].

The list of 14 characteristics of a good experimental design in Box and Draper [17] includes the ability to check models for lack of fit. The early stages of an experimental program often use 2^m factorials and their fractions to screen factors. To check whether a second-order model such as equation (13) is required, one or more trials are included at the center of the experimental region. An informal extension of this procedure is to augment the optimal design by inclusion of a few extra trials in unused regions of $\mathcal{X}$. A more formal approach to designs for model checking, using the methods of optimal design, is given by DuMouchel and Jones [18], who specify both a primary model, for which good estimation of the parameters is required, and secondary terms, which need to be detected if they are nonzero. It is hoped that the primary model will provide an adequate fit. Examples of designs and the exploration of the relationship with compound D-optimality are given in Chapter 20 of Atkinson *et al.* [1].

The first book in English on optimal experimental design was Fedorov [12]. Pukelsheim [19] focuses on theory, as does the shorter book of Fedorov and Hackl [20]. Atkinson *et al.* [1] is more concerned with applications and provides SAS code for the construction of many designs. In addition to the linear models covered in this article, methods are given for the optimal design of experiments for correlated data, generalized linear models and, in particular, in Chapter 17, for the design of experiments for nonlinear models. The papers in Berger and Wong [21] focus on recent applications of optimal design,

including some in the pharmaceutical industry. As with any topic, a large amount of information can be obtained by searching the Web. About 75% of the references on Google are to “optimal design” while 25% use the term *optimum design*.

ANTHONY C. ATKINSON

Orthogonal Arrays

Introduction and Motivating Example

We wish to conduct a simple experiment to determine the effects of two factors on a quantitative response Y . An experiment to investigate the effects of several factors on a response is referred to as a *factorial experiment* (see **Factorial Experiments**). Assume that each factor is to be observed at only two levels (two values), which we denote -1 and $+1$. If a factor is quantitative, but we decide to observe it at only two of its possible values, -1 is used to denote the smaller of the two levels.

Suppose that we decide to take a total of four observations (runs). At what combinations of values (called the *treatments*) should we observe the factors? We will represent the treatments that we observe for each run by a design matrix or array. Columns represent factors and rows runs. The entry in a given column and row indicates the level of the factor represented by the column that is observed for the run represented by the row. Table 1 gives three of several possibilities. Notice that, in all three designs, the first run consists of the treatment with factor 1 at level 1 and factor 2 at level 1.

A minimal requirement of any design is that it should allow us to estimate all the factor effects (main effects and interactions) that we believe are present. In this experiment, suppose that only main effects are present. Then a design should allow us to estimate the main effects of both factors. To investigate this, for each design we generated observations Y with value equal to the sum of the levels of the two factors plus random error (taken to be normal with mean 0 and standard deviation 0.1). We analyzed the data with statistical software using a main-effects-only analysis

of variance model (see **Analysis of Variance**) and the type-III sums of squares (SS). For more about this type of analysis, see [1, 2] or [3]. The results are summarized in Table 2.

For the first design, the software does not provide estimates of the sum of squares due to the main effects of factors 1 and 2. These sums of squares are estimates of the variation in the response due to these main effects. On reflection, it is not surprising that we do not obtain estimates. The effect of a factor is observed by changing its level and seeing how the response changes. For design 1, whenever we change factor 1 we also change factor 2. Hence, we cannot determine if observed changes in the response are due to factor 1, factor 2, or the sum of their effects. In this case, we say factors 1 and 2 are *completely aliased* (see **Aliasing in Fractional Designs**). In general, this occurs when the columns in a design corresponding to two different factors are perfectly correlated (a **correlation** of either 1 or -1). For design 1, the correlation between the four pairs of values is 1.

In the second and third designs, we obtain estimates of the main effects of factors 1 and 2. However, additional analysis reveals a problem with the second design. Suppose we had assumed that there were no main effects of factor 2 and fit a main-effects model that included only factor 1. The results (for both designs, 2 and 3) are summarized in Table 3.

As should be the case, for both designs the sum of squares for factor 2 is incorporated (added) into the error sum of squares and the total sum of squares is unchanged. However, for design 2 the effect of factor 1 has changed (increased). For design 3 the effect of factor 1 is unchanged.

The problem is that for design 2 the levels of factors 1 and 2 are correlated (the correlation is 0.5774). This is known as *collinearity* in regression and as *partial aliasing* in factorial experiments. When

Total	3	10.4370	3	8.6706

partial aliasing is present the effects of the two factors cannot be completely separated. It is manifested when the sum of squares for one effect (factor 1 in the example) changes when a second effect (factor 2 in the example) is removed from the model.

In design 3, the levels of factors 1 and 2 are uncorrelated (the correlation is 0). In this case, factor effects are independent of each other and the sum of squares for the **main effect** of factor 1 is the same whether or not the main effect of factor 2 is included in the model. When the levels of two factors are uncorrelated, the factors have a property known as *orthogonality*. Orthogonality is formally defined in the next section. Orthogonality is also equivalent (provided the levels are coded properly) to perpendicularity of vectors. When viewed as 4×1 column vectors, the two columns of design 3 are perpendicular.

This simple experiment illustrates the fact that to avoid aliasing (complete or partial), and thus obtain independent estimates of the effects of factors, it is desirable that every pair of factors in a design be orthogonal. This is formalized in the notion of an orthogonal array.

Definitions and Examples

In a factorial experiment, if all the level combinations of two factors appear in the same number of runs, the two factors are said to be *orthogonal*. A design is called *orthogonal* if all pairs of factors in the design are orthogonal. More generally, in a matrix two columns are said to be orthogonal if all possible combinations of symbols in the two columns appear equally often together. If all pairs of columns of a matrix are orthogonal, the matrix is said to be orthogonal. For the case where all factors have s

levels, we now define a rich class of designs that have this feature and even stronger properties.

Definition 1 Let S be a set of s symbols or “levels” denoted $0, 1, \dots, s-1$. An $N \times k$ matrix A with entries from S is called an *orthogonal array* with s levels, strength t ($0 \leq t \leq k$), and index λ if every $N \times t$ submatrix of A contains each t -tuple of symbols from S exactly λ times as a row. We use the notation $OA(N, k, s, t)$ to denote such an array.

Because there are s^t possible t -tuples of elements from S , an immediate consequence of this definition is that

$$N = \lambda s^t \quad (1)$$

In particular, equation (1) shows that λ is a function of N , s , and t so the parameters N , k , s , and t are sufficient to define an orthogonal array.

Orthogonal arrays as defined above are sometimes referred to as *symmetrical orthogonal arrays* (see for example [4]). Orthogonal arrays were first introduced by Rao [5, 6]. In the context of two-level factorial experiments, it is not uncommon to denote the elements of S -1 , $+1$ rather than 0 , 1 .

Example 1 An $OA(8, 4, 2, 3)$ is given in Table 4. Rows represent experimental runs and columns factors. Notice that every 8×3 submatrix (every selection of three columns of the matrix) has the property that all eight, three-tuples of elements of $S = \{0, 1\}$ occur exactly $\lambda = 1$ times as a row.

Example 2 An $OA(12, 11, 2, 2)$ with elements of S denoted by -1 and $+1$ is given in Table 5. Notice that every 12×2 submatrix has the property that all four two-tuples of elements of $S = \{-1, 1\}$ occur exactly $\lambda = 3$ times as a row.

-1	-1	-1	-1	-1	-1	-1	-1	-1	-1	-1

In some experiments it may not be possible or desirable to use the same number of levels for each factor. An extension of orthogonal arrays to the case where factors may have different numbers of levels is the following.

Definition 2 A *mixed orthogonal array*, denoted $OA(N, s_1^{k_1} s_2^{k_2}, \dots, s_v^{k_v}, t)$ of strength t is an $N \times k$ matrix where $k = k_1 + k_2 + \dots + k_v$ is the total number of factors, in which the first k_1 columns have symbols from $\{0, 1, \dots, s_1 - 1\}$, the next k_2 columns have symbols from $\{0, 1, \dots, s_2 - 1\}$, and so on, with the property that in any $N \times t$ submatrix every possible t -tuple occurs an equal number of times as a row.

Example 3 An OA(12, 2^4 , 3, 2) is given in Table 6.

Mixed orthogonal arrays are sometimes referred to as *mixed-level orthogonal arrays* or *asymmetrical orthogonal arrays*. Also, an $OA(N, s_1^{k_1}, s_2^{k_2}, \dots, s_v^{k_v}, t)$ is sometimes denoted by $L_N(s_1^{k_1} s_2^{k_2}, \dots, s_v^{k_v})$, when

the strength is assumed to be two. Mixed orthogonal arrays were studied as early as 1961 by Addelman and Kempthorne [7] and were called *asymmetrical orthogonal arrays* by Rao [8].

Construction and Tables of Orthogonal Arrays

A variety of techniques are available for constructing orthogonal arrays. For example, an s^{k-p} **fractional factorial** design of resolution $k - p + 1$ is an $OA(s^{k-p}, k, s, k - p)$. The N -run Plackett–Burman designs (see **Plackett–Burman Designs**), which are designs for experiments with all factors at two levels, can be generated cyclically given the first row. The second row is obtained from the first by shifting all entries to the right by one position and then placing the last entry in the first position. The third row is generated from the second row in the same way and this process continues until $N - 1$ rows are generated. All entries in the last row are -1 . You can verify that the 12-run Plackett–Burman design given previously is generated in this way. Table 7.5 of [4] lists the first row for 12-, 20-, 24-, 36-, and 44-run Plackett–Burman designs.

Most techniques involve the use of certain combinatorial objects (linear codes, mutually orthogonal Latin squares, Hadamard matrices) or abstract algebra (Galois fields, projective geometry). Consult [9] for details, as well as a wealth of information about orthogonal arrays. Extensive tables of orthogonal arrays exist (see for example [9, 10]). N. J. A. Sloane maintains an on-line library of orthogonal arrays at the web site <http://www.research.att.com/~njas/oadir/index.html>. One can also find Plackett–Burman designs at this web site.

Applications

Fractional Factorial Experiments

Some General Comments. Orthogonal arrays with two levels provide useful designs for two-level fractional factorial experiments with k factors (see **Fractional Factorial Designs**). In particular, an $OA(N, k, 2, t)$ yields a design matrix for an N -run experiment in which no factorial effect of order $w \leq t$ is aliased with any other factorial effect of

order $t + 1 - w$ or less. A design with this property is said to have *resolution* $t + 1$ (see **Factorial Designs, Resolution of**). While it is true that a standard 2^{k-p} fractional factorial design of resolution $k - p + 1$ is an $\text{OA}(2^{k-p}, k, 2, k - p)$, it is not true that every $\text{OA}(2^{k-p}, k, 2, k - p)$ necessarily be a standard 2^{k-p} fractional factorial design. In other words, an arbitrary $\text{OA}(2^{k-p}, k, 2, k - p)$ may exhibit complex aliasing, i.e., some higher-order interactions may be partially aliased (rather than fully aliased) with lower-order effects.

Data from an $\text{OA}(N, k, 2, t)$ can be analyzed as follows. Use a model with k factors that includes only main effects and all t and fewer factor interactions of the k factors. Fit the model using standard statistical software. When the number of runs is equal to the number of effects in the model use half-normal plots (see **Half-Normal Plot**) or Lenth's method (see **Lenth's Method for the Analysis of Unreplicated Experiments**). Consult [1, 2] or [3] for more on the analysis of data from a fractional factorial experiment.

More generally, symmetric orthogonal arrays with more than two levels provide useful designs for higher-level factorial experiments. Also, asymmetric orthogonal arrays are useful for constructing designs in mixed-level factorial experiments. See [4] for further discussion.

Main-Effects Plans. When two-factor and higher-order interactions are assumed to be negligible, a model that includes only main effects would be considered adequate for describing the relationship between the response and the factors (see **Main Effect Designs**). Designs in which all pairs of factors are orthogonal have desirable properties in that no main effects are aliased with each other. In 1946, Plackett and Burman [11] constructed a large collection of orthogonal designs that are $\text{OA}(4m, 4m - 1, 2, 2)$, where $4m$ is not a power of 2. The design in Table 5 is an example. Their designs are known as *Plackett–Burman designs* (see **Plackett–Burman Designs**) in the literature and it has become common practice to refer to all $\text{OA}(4m, 4m - 1, 2, 2)$ as Plackett–Burman designs. Selecting $F \leq 4m - 1$ columns of an $\text{OA}(4m, 4m - 1, 2, 2)$ yields a design with $4m$ runs that allows one to estimate the main effects of F factors without aliasing.

Screening Designs. Screening experiments (see **Screening Designs**) are used when one is interested

in investigating a large number of factors simultaneously, but only a few are thought to be *active* (have nonnegligible effects). In screening experiments it is usually only possible to run small fractions of the full factorial. As a consequence, such designs are likely to have low resolution. However, if one discovers that only a few factors are active it is desirable that the subdesign, called a *projection*, consisting only of the active factors be a full factorial. We typically do not know in advance which factors are likely to be active, so designs with the property that the projections onto all sufficiently small subsets of factors are full factorial designs are attractive. When the projection onto the active factors is a full factorial, a reanalysis of the data using only the active factors can be run as a full factorial and all main effects and interactions estimated.

Cheng [12] shows that certain orthogonal arrays on two symbols have this desirable projection property, making these orthogonal arrays useful for screening experiments. A design is said to be of *projectivity* p if, for every subset of p factors, a complete factorial design (possibly with some combinations replicated) is produced. If the two symbols in the orthogonal array are -1 and $+1$, the orthogonal array is said to have a *defining word of length* r if there exist r columns of the array with the property that the column whose i th row is the product of all the entries in the i th row of the r columns is either the vector in which all entries are 1 or the vector in which all entries are -1 . Cheng [12] shows that an $\text{OA}(N, k, 2, t)$ with $k \geq t + 1$ has projectivity $t + 1$ if and only if it has no defining word of length $t + 1$. For example, one can verify that the 12-run Plackett–Burman design (the $\text{OA}(12, 11, 2, 2)$ given in Table 5) has no defining word of length three and hence has projectivity three.

As an extension, one might also be interested in designs with the property that all projections onto a small number of factors be of resolution III (but not necessarily a complete factorial design). Such designs are said to have a hidden projection property. See [4] for more on this.

Optimal Designs for Response Surface Modeling

Suppose N units are observed in an experiment. On the i th, unit a response y_i and p explanatory variables (also called *predictors*, *regressors*, or *covariates*) $x_{i1}, x_{i2}, \dots, x_{ip}$ are measured, $1 \leq i \leq N$. Suppose

also that the response and explanatory variables are related by the following equation or *response surface model* (see **Response Surface Methodology**);

$$y_i = \beta_0 + \beta_1 x_{i1} + \cdots + \beta_p x_{ip} + \varepsilon_i \quad (2)$$

where the ε_i represent independent random errors that are assumed to be normally distributed with mean 0 and variance σ^2 . $\beta_0, \beta_1, \dots, \beta_p$ are unknown constants or parameters to be estimated. The model in equation (2) is sometimes referred to as a *first-order response surface model*. After appropriately scaling each x_{ij} , it may be plausible to assume all x_{ij} satisfy $-1 \leq x_{ij} \leq +1$. It is customary to arrange the values of the x_{ij} in an $N \times (p+1)$ model matrix

$$\mathbf{X} = \begin{pmatrix} 1 & x_{11} & \cdots & x_{1p} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & x_{N1} & \cdots & x_{Np} \end{pmatrix} \quad (3)$$

If the last p columns of $\mathbf{X}$ in equation (3) are an $\text{OA}(N, p, 2, t)$, using -1 and $+1$ to denote the levels, and if $t \geq 2$, then the resulting design is optimal (see **Optimal Design**) under a wide range of standard criteria such as A-, D-, and E-optimality. For example, the $\text{OA}(12, 11, 2, 2)$ given previously is a D-optimal 12-run design for a first-order response surface model with $p = 11$.

When equation (2) includes not only all linear terms (the $x_{i1}, x_{i2}, \dots, x_{ip}$) but also all cross-products of subsets of size q or less of these terms ($q \leq p/2$), then a design for which

$$\begin{pmatrix} x_{11} & \cdots & x_{1p} \\ \vdots & \ddots & \vdots \\ x_{N1} & \cdots & x_{Np} \end{pmatrix} \quad (4)$$

is an $\text{OA}(N, p, 2, t)$, using -1 and $+1$ to denote the levels, and for which $t \geq 2q$, is again optimal under a wide range of standard criteria such as A-, D-, and E-optimality. For $p/2 < q \leq p$, an $\text{OA}(N, p, 2, p)$ is needed in equation (4) for optimality. For example, an $\text{OA}(N, p, 2, t)$ with $t \geq 4$ is a **D-optimal design** for the model

$$y_i = \beta_0 + \sum_{j=1}^p \beta_j x_{ij} + \sum_{1 \leq j < \ell \leq p} \beta_{j\ell} x_{ij} x_{i\ell} + \varepsilon_i \quad (5)$$

with main effects and two-factor interactions.

Robust Parameter Design

In robust parameter design (see **Robust Design**), factors are divided into *control factors* (factors that are fixed once they are selected by a product designer) and *noise factors* (factors that are hard to control or may vary in normal use of a product). A typical objective is to find values of the control factors that make the product insensitive to variation in the noise factors. This can be accomplished by conducting experiments in which the noise factors are varied systematically in order to represent their variation in normal use. One strategy for designing such experiments is to choose separate designs for the control and noise factors. The design for the control factors is called the *control array* and the design for the noise factors the *noise array* (see **Product Array Designs**). Then, for each setting of the control factors in the control array, all settings in the noise array are observed. Such a design is called a *cross array*. The total number of runs in the cross array is the product of the number of factor settings in the control array and the number of factor settings in the noise array. Orthogonal arrays (symmetric or asymmetric) are often used for both the control and noise arrays. A name closely associated with robust parameter design is Genichi Taguchi. For more on robust parameter design, see [4].

Computer Experiments

There are situations in which a physical experiment is not feasible. In such cases it may be possible to describe the physical process of interest by a mathematical model implemented with code on a computer. One can then experiment with the code by varying the inputs. This is called a *computer experiment* (see **Computer Experiments**). For complex code that runs slowly (for example, taking 1 day for a single run), the number of runs is limited and one must design the computer experiment carefully. One principle is to select runs that are, in some sense, spread evenly over the design space. Orthogonal arrays have been used as the basis for designs in **computer experiments**. For k predictor variables each constrained to be between 0 and 1, and for some positive integer N , let $S = \{1/(N+1), 2/(N+1), \dots, N/(N+1)\}$. For this choice of symbols, an $\text{OA}(N^t, k, N, t)$ is an N^t -run design ($1 \leq t \leq k$) with the property that for any t columns,

if the rows are taken as points, we have a set of evenly spaced points on the t -dimensional unit cube $[0, 1]^t$. Thus, an $OA(N^t, k, N, t)$ provides a design with the property that when projected onto any t , or smaller, dimensional subspace (any subset of t or fewer columns), the points are spread evenly. When $t = 1$, this produces what is known as a *Latin hypercube design* (see **Latin Hypercube Designs**). Koehler and Owen [13] provide additional examples of the use of orthogonal arrays in computer experiments.

An Example

Hunter *et al.* [14] ran a screening experiment to study the effects of seven factors; initial structure (A), bead size (B), pressure treatment (C), heat treatment (D), cooling rate (E), polish (F), and final treatment (G), on the fatigue life of weld-repaired castings. Possible designs included an 8-run, resolution-III fractional factorial and a 16-run, resolution-IV fractional factorial. The eight-run design allows one to fit only a model with main effects but no interactions, and no separate estimate for error is possible. The 16-run design allows one to add some two-factor interactions (assuming others are negligible) and allows an estimate of the error. To reduce the number of runs, avoid aliasing main effects with each other, and still accommodate some two-factor interactions (assuming others are negligible – see [4, Chapter 8] for discussion of the actual aliasing present in the design), a 12-run $OA(12, 7, 2, 2)$ can be used. This was the design actually employed. The design and response (log lifetime) are given in Table 7.

The objective was to identify the factors that affect casting lifetime. A main-effects-only model can be fit to the data. Using a normal plot or Lenth's method, only factor F is identified as significant. A traditional analysis of variance gives a P value of 0.0556 and R^2 of 0.75. A follow-up analysis can be conducted by adding various subsets of all two-factor interactions with F to a model including all main effects. This process further identifies the FG interaction as significant (the P value for F is now 0.0144 and 0.042 for FG), with a marked improvement in the model fit (R^2 increases to 0.95). The conclusion is that polish and its interaction with the final treatment affect lifetime. Examining the factor effects indicates that setting F at its highest level and G at its lowest level produces the longest

Table 7 The $OA(12, 7, 2, 2)$ for the 12-run, seven-factor experiment, with the log of the observed lifetimes

A	B	C	D	E	F	G	log lifetime
+1	+1	-1	+1	+1	+1	-1	6.058
+1	-1	+1	+1	+1	-1	-1	4.733
-1	+1	+1	+1	-1	-1	-1	4.625
+1	+1	+1	-1	-1	-1	+1	5.899
+1	+1	-1	-1	-1	+1	-1	7.000
+1	-1	-1	-1	+1	-1	+1	5.752
-1	-1	-1	+1	-1	+1	+1	5.683
-1	-1	+1	-1	+1	+1	-1	6.607
-1	+1	-1	+1	+1	-1	+1	5.818
+1	-1	+1	+1	-1	+1	+1	5.917
-1	+1	+1	-1	+1	+1	+1	5.863
-1	-1	-1	-1	-1	-1	-1	4.809

lifetime. This is consistent with what one observes in the data in Table 7.

Plackett–Burman Designs

Construction of Plackett–Burman Designs

Plackett and Burman (PB) [1] provided us with a class of two-level orthogonal designs which now just are referred to as *PB designs*. If we restrict the name to only those designs introduced by Plackett and Burman, they exist for the number of runs $n = 4m$, $m = 1, 2, \dots, 25$ (except 23 which was given by Baumert *et al.* [2]).

Plackett and Burman used three ways of constructing these designs. One is cyclic generation. For a cyclic generated orthogonal array (see **Orthogonal Arrays**), it is possible to write down all the $n - 1$ contrast columns knowing only the sequence of ± 1 's in the first row. For instance for the 12-run PB design this string omitting the 1's and only writing down the signs is given by: $+ - + - - - + + - +$. Shifting this row cyclically one place 10 times and adding a row of minus signs produces a design matrix for the 12-run PB design. Adding an initial column of plus signs gives us the 12×12 Hadamard matrix (see **Projectivity in Experimental Designs**), shown in Table 1 where the 11 factors are denoted $x_A, x_B, \dots, x_K$.

Plackett and Burman [1] used this way of constructing orthogonal arrays for $n = 8, 12, 16, 20, 24, 32, 36, 44, 48, 60, 68, 72, 80$, and 84. For $n = 28, 52, 76$, and 100 they used block cycling and for $n = 40, 56, 64, 88$, and 96 their way of obtaining orthogonal arrays was by doubling. The technique of doubling can be explained as follows. Let H_n be a $n \times n$ Hadamard matrix with all entries in the first column equal to $+1$. The matrix $\begin{bmatrix} H_n & H_n \\ H_n & -H_n \end{bmatrix}$ is then a $2n \times 2n$ Hadamard matrix whose last $2n - 1$ columns constitute the orthogonal two-level array.

For $n = 2^k$ $n = 1, 2, 3, 4, 5$, and 6, PB designs coincide with the well known fractional factorial two-level designs (see **Fractional Factorial Designs**), which also are called *geometric designs* or sometimes *regular designs*. The rest of the PB designs are called *nongeometric designs* or sometimes *nonregular designs*. The signs for cyclic generation of the 20-, 24-, and 36-run PB designs are:

$$n = 20 : + + - - + + + - + - + - - \\ - - + + -$$

$$n = 24 : + + + + + - + - + + - - + + \\ - - + - + - - - - \\ n = 36 : - + - + + + - - - + + + + + \\ - + + + - - + - - - - + - + - \\ + + - - + -$$

How to obtain the other PB designs is described in great detail in [1]. PB designs are also available on Neil Sloane's web site: www.research.att.com/~njas/index.html#TABLES.

The rest of this article focuses on **projectivity** of PB design, methods for analyzing them, an example to show their efficiency for experimentation and some techniques that can be used to construct designs with efficient run sizes and good projective properties from PB designs.

Projectivity of Plackett–Burman Designs

PB designs were introduced as main-effects plans (see **Main Effect Designs**), and nongeometric PB designs have for a long time been considered to be important **screening designs** in situations where only main effects were expected to show up. Later (Lin and Draper [3], Box and Bisgaard [4], Cheng [5], Box and Tyssedal [6], and Samset and Tyssedal [7]) it was discovered that the nongeometric PB designs have quite remarkable projective properties compared to the geometric fractional **factorial** designs. The concept of design projectivity for two-level designs was defined by Box and Tyssedal [6]. A $n \times k$ design with n runs and k factors each at two levels is said to be of projectivity P if the design contains a complete 2^P factorial in every possible subset of P out of the k factors, possibly with some points replicated. Box and Tyssedal [6] describe such designs as (n, k, P) screens.

Box and Tyssedal [6] were able to prove three propositions for orthogonal two-level arrays that can be used for classifying PB designs with respect to being of projectivity $P = 2$ and only two or of projectivity at least $P = 3$ (see **Projectivity in Experimental Designs**). Later Samset and Tyssedal [7] discovered by a computer search that PB designs with $n = 68, 72, 80$, and 84 also are $(n, n - 1, 4)$ screens. An orthogonal design with $k = n - 1$ is called *saturated*. A complete listing of the projectivity of saturated PB designs is given in Table 2.

2 Plackett–Burman Designs

Table 1 A 12×12 Hadamard matrix where the last 11 columns constitute a 12-run PB design

	x_A	x_B	x_C	x_D	x_E	x_F	x_G	x_H	x_I	x_J	x_K
1	1	-1	1	-1	-1	-1	1	1	1	-1	1
1	1	1	-1	1	-1	-1	-1	1	1	1	-1
1	-1	1	1	-1	1	-1	-1	-1	1	1	1
1	1	-1	1	1	-1	1	-1	-1	-1	1	1
1	1	1	-1	1	1	-1	1	-1	-1	-1	1
1	1	1	1	-1	1	1	-1	1	-1	-1	-1
1	-1	1	1	1	-1	1	1	-1	1	-1	-1
1	-1	-1	1	1	1	-1	1	1	-1	1	-1
1	-1	-1	-1	1	1	1	-1	1	1	-1	1
1	1	-1	-1	-1	1	1	1	-1	1	1	-1
1	-1	1	-1	-1	-1	1	1	1	-1	1	1
1	-1	-1	-1	-1	-1	-1	-1	-1	-1	-1	-1

We observe that all saturated geometric fractional factorial designs are of projectivity $P = 2$ and only 2. However for all of them it is possible to remove $n/2 - 1$ columns and obtain a $(n, n/2, 3)$ screen (Box and Tyssedal [6]).

In their computer search Samset and Tyssedal [7] also discovered that all PB designs with projectivity $P = 3$ have the hidden projection properties (Lin and Draper [3] and Wang and Wu [8]) that all main-effects and two-factor interactions for any four factors are estimable under the assumption that higher-order interactions are negligible.

Methods for Analyzing Plackett–Burman Designs

Nongeometric designs have more complex aliasing (see **Aliasing in Fractional Designs**), than the geometric designs (Lin and Draper [9]). For instance in a 12-run PB design every **main effect** may be partially aliased with 45 two-factor interactions and a single two-factor interaction will appear in the alias pattern of all main effects not involved with this two-factor interaction. As a result standard

methods often used for analyzing unreplicated two-level designs such as normal and half-normal plots (Daniel [10]), or more quantitative methods such as **Lenth's method** (Lenth [11]) may be of little value since these methods are based on being able to separate active contrasts from contrasts estimating only noise.

However, several methods are available also for analyzing these designs. These can mainly be classified as effect based or factor based. Effect-based methods aim at identifying significant effects. A model consisting of main effects and interactions (see **Interactions**), is assumed to give an adequate approximation of the response. The principle of effect heredity; i.e., an interaction is excluded from the model unless at least one (weak heredity) or both (strong heredity) of the main effects associated with the interaction also are included, is often a precept. Examples of such methods can be found in Hamada and Wu [12] and Chipman *et al.* [13]. An effect-based method that doesn't depend on the heredity principle is given in Tyssedal and Kulahci [14]. Factor-based methods aim at identifying active factors and they are less dependent on model assumptions, heredity included (see **Projectivity in Experimental Designs**). Their drawback may be that if the factor effects are small relative to the level of noise, it may be difficult to discriminate among several candidate sets of active factors. Examples of such methods are given in Box and Meyer [15], Kulahci and Box [16] and Tyssedal and Samset [17]. For both methods it is crucial that sparsity of either effects or factors respectively can be assumed. In addition projective properties of the

Table 2 The projectivity of Plackett–Burman designs

Screens	Number of runs, n
$P = 2$	4, 8, 16, 32, 40, 56, 64, 88, 96
$P = 3$	12, 20, 24, 28, 36, 44, 48, 52, 60, 76, 100
$P = 4$	68, 72, 80, 84

design used are conclusive in order for a factor-based search to work well (see **Projectivity in Experimental Designs**).

An Example

Montgomery *et al.* [18] published a paper in quality engineering with the title: *Some Cautions in the Use of Plackett–Burman designs*. They used a 12-run PB designs, see Table 1, and data were simulated from the following model

$$y = 200 + 8x_A + 10x_D + 12x_E - 12x_Ax_D + 9x_Ax_E + \varepsilon \quad (1)$$

where ε is a normally distributed random error term with mean 0 and variance 9. The columns for the factors x_A , x_D , and x_E correspond to the ones in Table 1. We note that the model obeys both the weak and the strong heredity principle. Montgomery *et al.* [18] used normal **probability plots** in combination with the method suggested by Hamada and Wu [11] for the analysis. Due to large two-factor interactions these two methods are not very suitable for analyzing this response and their conclusion was that a sequential strategy, starting with a 2_{III}^{11-7} fractional factorial and adding two additional follow-up runs in this situation outperformed a PB design.

Now suppose we instead chose to use a factor-based method as proposed in Tyssedal and Samset [17] which we will call a projective-based search. This method exploits the projective properties of the design (Lin and Draper [3] and Box and Tyssedal [6]). In particular, the 12-run PB design projects into a 2^1 design replicated six times in any one factor. It projects into a 2^2 design replicated three times in any two factors and it projects into a 2^3 design with four runs replicated in any three factors.

Thereby assuming at most three active factors, we can investigate how well every set of k factors explain the data $1 \leq k \leq 3$, by examining the fit for replicated runs, calculating

$$\hat{\sigma}^2 = \frac{1}{\sum_{i=1}^s (r_i - 1)} \sum_{i:\text{replicated}} \sum_{j=1}^{r_i} (y_{ij} - \bar{y}_i)^2 \quad (2)$$

where s is the number of runs replicated and r_i is the number of replications for replicated run number i .

Table 3 Results from a projective-based search on the response given in equation (1)

1 active		2 active		3 active	
$\hat{\sigma}$	Factor	$\hat{\sigma}$	Factors	$\hat{\sigma}$	Factors
18.15	x_E	16.78	x_A, x_E	4.26	x_A, x_D, x_E
24.62	x_F	16.80	x_C, x_E	8.05	x_B, x_E, x_I
24.75	x_A	17.40	x_E, x_I	8.29	x_C, x_E, x_J
24.87	x_D	17.66	x_B, x_J	8.34	x_C, x_E, x_H
24.87	x_G	17.98	x_E, x_F	9.25	x_D, x_E, x_F

Sets of factors that give small values of $\hat{\sigma}^2$ are candidates for being declared active.

We simulated a new set of data from the model given in equation (1). A candidate list showing the five set of factors minimizing $\hat{\sigma}$ for $k = 1, 2$, and 3 is given in Table 3. Clearly assuming at most three active factors one would in this case end up with x_A , x_D , and x_E after 12 runs and no heredity assumptions need to be imposed on the model.

In cases where several set of factors have approximately the same $\hat{\sigma}$, backward regression on a model fully expanded with main effects and interactions will sometimes eliminate the ambiguity. For more on this method we refer to Tyssedal and Samset [17] and Tyssedal *et al.* [19] where also a successful application of the 12-run PB design is given. Finally we remark that in this case a search through all possible models consisting of main-effects and two-factor interactions for up to three factors would work equally well. The success of such an effect-based search, however, depends on the underlying model (see **Projectivity in Experimental Designs**).

Construction of Designs from PB Designs

The **foldover** of a $n \times k$ two-level design is the design obtained when all mirror images of the original design's runs are added in addition to a column where the first n entries are +1 and the last n entries are -1 (see **Projectivity in Experimental Designs**). If $\mathbf{X}$ is a nongeometric PB design, Samset and Tyssedal [7] found by computer search that the foldover is always of projectivity $P = 4$ or a $(2n, n + 1, 4)$ screen except for $n = 40, 56, 88$, and 96. Designs constructed in this way from PB designs will always have the hidden projection property that all main-effects and two-factor interactions of any five factors can be estimated (Samset and Tyssedal [7]).

A two-level design with more than $n - 1$ factors is called *supersaturated* (see **Supersaturated Designs**). Lin [20] introduced a new class of supersaturated designs using half-fractions of orthogonal arrays, i.e., PB designs. For any arbitrary column the $n/2$ rows corresponding to either $+1$ or -1 in that column will constitute a design allowing $n - 2$ factors in $n/2$ runs. If the PB designs used for construction is of projectivity $P = 4$, the supersaturated designs will have projectivity at least $P = 3$, Samset and Tyssedal [7].

PB designs have also been suggested for use in **split-plot** experimentation (see **Split-Plot Designs**), both as whole-plot and subplot arrays in order to reduce the number of individual tests (Kulahci and Bisgaard [21] and Tyssedal and Kulahci [14]).

Concluding Remarks

Due to their complex alias pattern practitioners have often been warned against using nongeometric PB designs. This warning seems to be exaggerated and may in some situations act as a barrier against efficient experimentation. Nongeometric PB designs provide us with a lot more design alternatives. If factor sparsity can be assumed their excellent projective properties compared to the geometric fractional factorials allow us to identify active factor spaces [22] under weak assumptions on the underlying model, and their hidden projection properties are very attractive if the model is adequately approximated in terms of main-effects and two-factor interactions.

One of the reasons why these designs are not used as often as they should is the lack of good available software to do the analysis. In the future more effort is needed to overcome this unnecessary obstacle.

JOHN TYSSEDAL

Projectivity in Experimental Designs

Concept and Usefulness

Projectivity concerns the properties of a **factorial** design when it is restricted to a subset of experimental factors. Box and Tyssedal [1] defined projectivity of two-level designs as follows: A $n \times k$ design with n runs and k factors each at two levels is said to be of projectivity P if the design contains a complete 2^P factorial in every possible subset of P out of the k factors, possibly with some points replicated. Box and Tyssedal [1] describe such designs as (n, k, P) screens. In general a $n \times k$ design with all factors at s levels is said to be of projectivity P if every subset of P factors out of possible k contains a complete s^P factorial design, possibly with some points replicated. This article will present results for two-level designs only.

The concept of projectivity is related to strength of orthogonal arrays (Rao [2], *see* **Orthogonal Arrays**), but differs in that complete copies of a 2^P factorial are not required in order to have projectivity P . Projectivity is also related to the resolution of a design (Box *et al.* [3], *see* **Factorial Designs, Resolution of**). A design is of resolution R if no p -factor effect is confounded with any other effect containing less than $R - p$ factors. For geometric fractional factorial designs (*see* **Fractional Factorial Designs**); that is a $1/2^s$ fraction of a 2^k factorial it is always the case that $P = R - 1$ [1].

The rationale for considering projection properties of **screening designs** was first pointed out by Box *et al.* [3] and further explained in Box and Tyssedal [4]. In factor screening a model that often sufficiently approximates reality is that out of a larger number k of tested factors only a small subset, typically two or three, maybe four, are expected to really affect a particular response. This is known as *factor sparsity* and tells us that out of the whole k dimensional factor space there is an active subspace of lower dimension within which most of the changes in the measured response occur. When choosing an appropriate design for the experimental investigation, it is then of importance to consider projections of the design on to small subsets of factors.

Statistically, projectivity P implies that all main effects and all interactions of any P factors are estimable with no **bias** if the other factors are inert, but its usefulness for factor screening goes beyond that of **estimation** capacity. If our candidate set under investigation contains the true active factors, replicated runs have the same expected value. Thereby a model independent estimate of the error variance may be obtained regardless of any functional relationship, and the ability of a subset of factors to explain the variation in the response may be evaluated with rather weak assumptions on the underlying model. A pretty common assumption for analyzing a screening experiment is to assume that a model consisting of main effects and interactions gives an adequate approximation of the response. Also the principle of effect heredity (*see* **Plackett–Burman Designs**), is often a precept. These assumptions cannot be relied upon in every situation, Box and Tyssedal [4]. The importance of taking projective properties into account is that it may enable us to identify the active subspace without necessarily imposing restrictive assumptions on the underlying model. A more thorough investigation of the real relationship between design factors and responses can then be performed once the active subspace is identified.

The rest of this article will focus on projective properties of two-level designs, an example to illustrate how such properties can be taken advantage of when a factor screening is performed and some techniques that can be used to obtain designs with good projection properties in various experimental situations.

Projective Properties of Two-Level Orthogonal Arrays

Orthogonal two-level designs may be constructed from Hadamard matrices. A Hadamard matrix is a $n \times n$ matrix with entries ± 1 where rows and columns are pairwise orthogonal. Given a Hadamard matrix, H , an equivalent matrix with all elements in the first column equal to $+1$ can be obtained by multiplying by -1 each element in every row of H whose first element is -1 . The remaining $n - 1$ columns must have half 1 's and half -1 's and constitute an orthogonal two-level design that can accommodate $n - 1$ factors in n runs. Orthogonal designs with $k = n - 1$ are called *saturated*.

2 Projectivity in Experimental Designs

When $n = 2^k$ one type of two-level design can be written down as follows. In the first column -1 and $+1$ are alternated. The second column consists of alternating pairs of -1 's and $+1$'s. In general the length of the string of -1 's and $+1$'s doubles for each column up to column k which consists of 2^{k-1} -1 's followed by 2^{k-1} $+1$'s. The rest of the columns are then all possible interaction columns between these k columns. Designs written down in this way are known as the *fractional factorials* (see **Fractional Factorial Designs**), sometimes called *geometric designs* or *regular designs*. The rest of the orthogonal two-level arrays are called *nongeometric designs* or sometimes *nonregular designs*. A necessary condition for these designs to exist is that $n \equiv 0 \pmod{4}$.

Now let H_n be a $n \times n$ Hadamard matrix with all elements in the first column equal to $+1$. Then a $2n \times 2n$ Hadamard matrix may be constructed by the following technique: $H_{2n} = \begin{pmatrix} H_n & H_n \\ H_n & -H_n \end{pmatrix}$, called *doubling*. The last $2n - 1$ columns constitute a $2n \times 2n - 1$ orthogonal array. Another way of obtaining orthogonal arrays is by cyclic generation (see **Plackett–Burman Designs**). Box and Tyssedal [1] were able to prove three propositions that are useful for determining the projectivity of an orthogonal two-level array.

- A saturated design obtained from a doubled $n \times n$ Hadamard matrix is always of projectivity $P = 2$ and only 2.
- A saturated design obtained from a cyclic orthogonal array is either a geometric factorial orthogonal array with $P = 2$ and only 2, or else has projectivity at least $P = 3$.
- Any saturated two-level design obtained from an orthogonal array containing $n = 4m$ runs, with m odd, is of projectivity at least $P = 3$.

The last result is also in agreement with a published result in Cheng [5].

All saturated fractional factorials can be obtained from a doubled $n \times n$ Hadamard matrix and are therefore projectivity $P = 2$ and only two designs. However for all of them it is possible to remove $n - 1$ columns and obtain a $(2n, n, 3)$ screen [1]. If the saturated design obtained from H_n is of projectivity $P = 3$, the design obtained from doubling H_n and then removing the column with $+1$ for the first

n runs and -1 for the last n runs will be a $(2n, 2n - 2, 3)$ screen.

It is interesting to note that for $n = 8$ it is only possible to obtain a $(8, 4, 3)$ screen whereas the orthogonal array for $n = 12$ is cyclic generated and provides us with a $(12, 11, 3)$ screen. Hall [6] showed it was possible to construct five 16-run orthogonal arrays. One provides us with the well-known fractional factorial design from which a $(16, 8, 3)$ screen can be constructed. For the four others $(16, 12, 3)$ screens can be obtained from three of them and a $(16, 14, 3)$ screen can be obtained from the fourth [4].

An important class of two-level designs was derived by Plackett and Burman (PB) [7] (see **Plackett–Burman Designs**). Using the three propositions above, all PB designs can be classified with respect to being of projectivity $P = 2$ and only 2 or of projectivity at least $P = 3$ (Box and Tyssedal [1], see **Plackett–Burman Designs**). Later Samset and Tyssedal [8] discovered by a computer search that PB designs with $n = 68, 72, 80$, and 84 also are of projectivity $P = 4$.

An Example

To show the usefulness of exploiting projective properties in the search for active factors, assume a 12-run PB design (see **Plackett–Burman Designs**) in the 11 factors $x_A, x_B, \dots, x_K$, has been performed and that y is related to the three factors x_A, x_B , and x_C through the functional relationship

$$E(y) = 2x_A + 0.8x_B + \frac{2}{0.4x_B + x_Ax_Bx_C + 2} \quad (1)$$

Noise from a normally distributed error term with mean 0 and standard deviation $\sigma = 0.3$ was added and the projective-based search given in Tyssedal and Samset [9] and Tyssedal *et al.* [10] (see also **Plackett–Burman Designs**) was used to identify the active factors.

The two first columns of Table 1 show the five subspaces of three factors giving the best fit in a projective-based search. The subspace consisting of the three factors x_A, x_B , and x_C is clearly the one that best explains the variation in the data. The two last columns show the result of a search through all possible three-factor models consisting of main effects and two-factor interactions, a rather common

precept for a search based on the heredity principles. We notice that only x_A is included in the five candidate sets having the smallest estimated σ . In fact with zero noise and all three-factor interactions assumed inert, x_B and x_C are not included in the 10 subspaces of three factors giving the best fit.

A Bayesian approach to perform a factor based search is given in Box and Meyer [11].

Some Techniques Used to Construct Designs with Good Projection Properties

The **foldover** of a $n \times k$ two-level design is the design obtained when all mirror images of the original design's runs are added in addition to a column where the first n entries are $+1$ and the last n entries are -1 . Let $\mathbf{1}$ be a $n \times 1$ vector of ones. The foldover, $\tilde{\mathbf{X}}$, of a two-level design $\mathbf{X}$ is given by $\tilde{\mathbf{X}} = \begin{bmatrix} \mathbf{X} & \mathbf{1} \\ -\mathbf{X} & -\mathbf{1} \end{bmatrix}$.

Zeiden and Zemach [12] showed that the foldover of a $n \times k$ orthogonal two-level design of strength 2 is a $2n \times (k+1)$ orthogonal two-level design of strength 3 and therefore according to Cheng [5] also a projectivity $P = 4$ design in $k+1$ factors if n is not a multiple of 8.

Orthogonal two-level arrays have some important hidden projections properties [13, 14]. Assume interactions involving more than two factors can be neglected. The following results are due to Cheng [5] and Cheng [15] respectively.

- If n is not a multiple of 8, then in the projections on to any four factors, all main effects and two-factor interactions are estimable.

Table 1 A comparison between two searches for identifying three active factors in a 12-run PB design. One is a projective-based search. The other is a search where the three-factor interaction is neglected

Projective-based search		Neglecting interactions with three or more factors	
Factors in model	$\hat{\sigma}$	Factors in model	$\hat{\sigma}$
x_A, x_B, x_C	0.23	x_A, x_H, x_I	0.57
x_A, x_F, x_G	0.62	x_A, x_G, x_J	0.73
x_A, x_D, x_J	0.63	x_A, x_E, x_G	0.76
x_A, x_H, x_I	0.64	x_A, x_D, x_F	0.80
x_A, x_G, x_J	0.64	x_A, x_G, x_K	0.85

- If n is not a multiple of 16, then in the projections on to any five factors in a $P = 4$ design, obtained by foldover, all main effects and two-factor interactions are estimable.

Let $\mathbf{X}$ be a $(n, k, 3)$ screen. The design $\begin{bmatrix} \mathbf{X} & \mathbf{X} \\ \mathbf{X} & -\mathbf{X} \end{bmatrix}$ obtained from doubling $\mathbf{X}$ is then a $(2n, 2k, 3)$ screen. Note that $\mathbf{X}$ does not have to be orthogonal. The 68-run PB design is of projectivity $P = 4$. Lin [16] introduced a new class of supersaturated designs (*see Supersaturated Designs*), using half-fractions of Hadamard matrices. Such a construction normally reduces the projectivity by one [8]. A $(34, 66, 3)$ screen can then be constructed using an arbitrary column in the 68-run PB design as a branching column [8]. From this design a $(68, 132, 3)$ screen can be constructed by doubling.

Foldover and doubling have an interesting coupling to split-plot experimentation (*see Split-Plot Designs*). Suppose for each level combination of the whole-plot factors, two runs as mirror image pairs are used at the subplot level. The corresponding design can be written as

$$\begin{bmatrix} \mathbf{W} & \mathbf{S} \\ \mathbf{W} & -\mathbf{S} \end{bmatrix}$$

where $\begin{bmatrix} \mathbf{W} \\ \mathbf{W} \end{bmatrix}$ contains the whole-plot factors and $\begin{bmatrix} \mathbf{S} \\ -\mathbf{S} \end{bmatrix}$ the subplot factors. $\mathbf{W}$ and $\mathbf{S}$ may be different or equal. For instance if $\mathbf{X}$ is a $(n, k, 3)$ screen, $\mathbf{W} = \mathbf{S} = \mathbf{X}$ gives us a split-plot design of projectivity $P = 3$ that can accommodate n whole-plot factors and n subplot factors. For more details on these designs (see Tyssedal and Kulahci [17]).

Concluding Remarks

The reason it is important to focus on projective properties is the need to be able to identify active subspaces of factors without necessarily imposing restrictive assumptions on the underlying model. Nongeometric designs have very favorable projective properties compared to geometric ones, and from that perspective seem to be the preferable choice when many factors need to be investigated

4 Projectivity in Experimental Designs

in few runs and factor sparsity can be assumed. Many of the nongeometric designs have also very favorable hidden projection properties that essentially increase their projectivity by one if the model is adequately approximated by means of main effects and two-factor interactions. Such designs have therefore a great potential for use in screening experimentation and more attention should be paid to their use.

JOHN TYSSEDAL

Randomization in Experimental Designs

In an experiment to compare several treatments or factor settings, randomization is used as a standard method for deciding which treatment is assigned to each of the experimental units. Randomization is a means to relax the condition of *ceteris paribus* (= all other things being equal). This is quite popular in sports, when the conditions that cannot be made equal for the contestants are allotted by a random process. The argument is that in a large number of cases the different random conditions will cancel out and on the average the better will win.

Therefore, a large number of papers (like e.g. [1]) stress the fact that randomization allows drawing conclusions on **causality** even if there are uncontrollable outer influences, i.e. factors that may influence the experimental outcome but cannot be controlled by the experimenter. The classical example of such a factor is soil quality in agricultural experiments. Further examples of such factors that come to mind in the case of industrial experiments are variations in the raw materials or varying ambient conditions.

To explain the idea, we consider the comparison of two treatments for bending metal plates. The variable of interest is the reduction of material thickness. There are 16 metal plates available for an experiment. Now assume that (unknown to the experimenter) the plates come from two different batches, such that the plates from the first batch are much softer, leading to a higher reduction in thickness. For simplicity, consider the situation where there is no true difference between the two methods. Clearly, if we bend more of the soft plates with method A and more of the hard plates with method B, we will observe that method A on the average produces a higher reduction of thickness. Since we do not even know that the material comes from two batches, it is impossible to allocate them evenly to the two treatments. Here randomization is the solution: If the set of plates that receive method A is a simple random sample of size 8 taken from the set of 16 plates, we observe that the mean reduction of thickness under A *on the average over all possible outcomes of the randomization* is the same as the mean reduction of thickness under B.

However, there is more to randomization than that. In randomization theory, the randomization is used to

introduce a **correlation** structure on the observations, which can be used to justify a model for the analysis of the experiment.

This observation was first pointed out by R. A. Fisher. In his book *The Design of Experiments* [2, 3], he explains how the design of an experiment determines a large part of the properties of the data. He used a sensory experiment (the “lady tasting tea”) to introduce the “principles of experimentation”, which include randomization as a central part.

When describing randomization schemes, he shows that the randomization itself justifies properties of the distribution of the data, which therefore need not be checked by an analysis of the **residuals**, but which are a mathematical fact. Fisher explains that “the purpose of randomisation . . . is to guarantee the validity of the test of significance” [3, p. 64].

To explain this concept, we return to the example with the reduction of thickness of plates. The concept is based on the idea of a hypothetical observation. For each plate i , the number η_i is the hypothetical reduction of thickness that we would measure on the i th plate, if this was bent with a standard procedure. It is clear that η_i is unknown and cannot be observed. We have no information on the distribution of the η_i . It would be rather daring to assume that they are independent identically distributed (and normal). So we make no assumption on them at all. We do make an assumption on the effects of the treatments, however. For each of the two treatments, we assume that there is an effect τ_j , which acts additively on the η_i values. More precisely, consider a plate with the hypothetical observation η . If this plate is treated with method j , then we can write the truly observed material thickness y of this plate as

$$y = \eta + \tau_j. \quad (1)$$

We might of course give each plate a name (for instance “1” to “16”). These names are assigned at random. More precisely, we put the plates on a staple and then randomly select one permutation π among the $16! = 2 \times 10^{13}$ possible permutations of 1, . . . , 16. Then the name “1” is given to the $\pi(1)$ th plate, the name “2” to the $\pi(2)$ th plate, and so on. Since π is randomly selected, $\eta_{\pi(1)}$ is a random variable and the distribution of $\eta_{\pi(1)}$ is the same as that of $\eta_{\pi(2)}$ or of any $\eta_{\pi(i)}$ for $1 \leq i \leq 16$. Also, the joint distribution of $\eta_{\pi(1)}$ and $\eta_{\pi(2)}$ is the same as that of any other pair $\eta_{\pi(i)}$ and $\eta_{\pi(j)}$ for $1 \leq i < j \leq 16$.

2 Randomization in Experimental Designs

We use an experimental design that prescribes for each *name*, what treatment the plate *with that name* will get. Formally, the experimental design d therefore is a mapping from the set of all names to the set of treatments. The plate with name i will receive treatment $d(i)$. For instance, the design might be such that plates with names “1”, “3”, ..., “15” are bent with method A, while plates with names “2”, “4”, ..., “16” are bent with method B. Owing to the randomization used, the 8 plates assigned to each treatment are a random sample from the 16.

We then do the experiment in the order in which the plates lie on the staple. Note, however, that in our notation, y_i refers to the observation on the plate with name “ i ”, not on the i th observation that is made.

For the observation y_i we get from equation (1) that

$$y_i = \tau_{d(i)} + \eta_{\pi(i)}. \quad (2)$$

Then $\eta_{\pi(1)}$ has the same expectation and variance as any other $\eta_{\pi(i)}$, while the correlation between $\eta_{\pi(i)}$ and $\eta_{\pi(j)}$ is the same as that between any other two. Therefore the vector of observations $\mathbf{y} = [y_1, \dots, y_{16}]^T$ follows a linear model: the observations have the same mean vector and the same variance–**covariance** structure as the one-way classification model with a random overall mean. That is, they have the same joint distribution as if they followed the linear model

$$y_i = \tau_{d(i)} + m + e_i \quad (3)$$

where m is a random variable with unknown mean and variance and the e_i are independent identically distributed errors. It follows that the difference between the means of the two treatments is an unbiased estimate of the difference $\tau_1 - \tau_2$ between the two effects, and that the usual estimate for the variance from the one-way classification model (3) is an unbiased estimate of its variance.

The reader should observe that the randomization procedure described above randomizes the order in which the treatments are applied: We do not bend the plate with name “1” as the first one, but the plate that lies on top of the staple. Since the order of the treatments is determined by the names, the treatments are applied in a random order. Hence, a possible time trend in the experiment will not cause **bias**, it will be part of the η . The randomization will also work in cases in which run order is really the only thing that, in principle, distinguishes one observation from

another. For example, suppose we want to run an experiment to test different techniques to throw a ball at some target. Unlike the metal plates, where there is a physical experimental unit associated with each observation, here the same ball and the same thrower is used for each experimental run. Then the randomization process will only permute the order.

Returning to the example with the plates, now assume the experimenter found out about the two batches and he/she knows which plate comes from which batch. Then we will want to assign four plates from each batch to each treatment. This can be achieved by blocking (*see* **Blocking**): the plates will be separated into two blocks of size 8 each. The names now are given by double indices “ (i, j) ”, where $i = 1$ or 2 indicates the block and $j = 1, 2, \dots, 8$ indicates the number of the plate within the block. The experimental design d might then prescribe that plates with names $(1, 1), \dots, (1, 4)$ and $(2, 1), \dots, (2, 4)$ will receive treatment 1, while the others receive treatment 2. The experimenter will separate the two groups and randomly determine which of the groups is called *block 1* and which *block 2*. Furthermore, he/she will randomly order the numbers within the batches, independently for each batch. This procedure implies that η of the plate with number $(1, 1)$ will have the same expected value and the same variance σ^2 as that of any other (i, j) , while the covariance between (i, j) and (r, s) can take one of two values: ρ_1 if $i = r$ and $j \neq s$ or ρ_2 if $i \neq r$. Note that this is the same variance–covariance structure as in a simple block model with random block effects and with a random mean

$$y_{ij} = \tau_{d(i)} + m + b_j + e_{ij} \quad (4)$$

Therefore, the analysis can be done in the simple block model.

It is important to note that the correct model for the bending experiment depends on which randomization was done. A detailed explanation of the connection between the randomization and the model can be found in [4, 5].

It is clear in the example mentioned above that blocking is done to increase precision. The variance of the estimated treatment difference is proportional to $\sigma^2 - \rho_1$, which can become small if the blocks are homogeneous, i.e. the observations from the same block are highly correlated and ρ_1 is large. In industrial experiments, there is a second motivation for the use of blocks. If the experiment is done as a series

of runs that are carried out one after the other, there always is the possibility of a time trend. Therefore, the order of the experimental runs should be randomized. However, often there are factors that are difficult to change, and it might be preferable to change the levels of a certain factor as little as possible. This can be realized by a blocked experimental design, in which the hard-to-change factor is held at the same level within each block. Say, we use a **fractional factorial design** (see **Fractional Factorial Designs**) with five two-level factors in 16 runs. Assume the first factor is hard to change. Then it might make sense to separate the runs into four groups of four each, such that the setting of factor 1 in each group is constant. Then we will randomize the order in which these four groups are done and the order of the runs in each group. This will lead to a block design, where the effect of factor 1 is confounded with the random block effect. Note that this allows **estimation** of the effect of factor 1, but that this factor has another (generally larger) variance than the other factors. Designs of that sort are called *split-plot designs* (see **Split-Plot Designs** and e.g. [6]).

As we try to point out in this article, the great advantage of randomization lies in the justification of a model for the analysis. With proper randomization a model can be made “valid”. Strictly speaking, the word *valid* means only that the estimates from that model are unbiased and that their variances (and the estimates for the variances) are the same as if that model were true (see [5]). However, randomization cannot guarantee normality of the errors and therefore it cannot guarantee normality of the estimates. Fisher himself did not consider this a large problem. In his book on experimental design, he explains the concept of permutation tests, and [3, p. 48] shows for an example that the permutation test leads to the same results as the t -test. He also quotes a paper [7] by Eden and Yates as indication that the F -test is valid, even if the data are nonnormal. Eden and Yates used data from a uniformity trial and a permutation test to compare the empirical distribution of the F statistic to the theoretical F distribution, where the empirical distribution was derived with a permutation test. A uniformity trial is an experiment where all experimental units receive the same treatment. They showed that the data from their uniformity trial were highly skewed, but that the empirical distribution function of the F statistic was very near to the theoretical function. Hence, they concluded that the

nonnormality of their data was not a problem for the validity of the F -test. Fisher [3, p. 57] quotes this experiment and states that Eden and Yates “have demonstrated how closely the theoretical distribution was verified in material that was far from normal”.

However, Fisher’s point of view is slightly too optimistic. As Yates [8, p. xix] points out himself, the Eden and Yates example in [7] is not quite as convincing as it was thought to be at the time: each original data point used for their simulation was the mean of 8 highly skewed observations. Being the mean, it was not as skewed as the single values. Yates wrote: “A random selection of one unit out of each group should have been taken, as taking the means eliminated most of the **skewness** from the data; unfortunately this was not noted at the time.” In spite of the fact that their data were not as nonnormal as it seemed, the method to check the validity of the F -test was an ingenious one, which since that time has been used frequently by other authors. This method also provides an alternative to the parametric test if the empirical distribution function should not fit the theoretical distribution, namely a variant of the permutation test, which is called *randomization test* (see e.g. [9]).

Because the numerator of the t -test or the F -test is generally the mean or a function of the mean, the validity of the normality assumption is largely supported by the central limit theorem, in all but the smallest examples. This explains why in the majority of cases normality is indeed not a problem. If problems arise, they are usually due to **outliers** in the data or due to the fact that the number of different possible permutations may be too small.

For small fractional factorial designs this can indeed be the case. Note that in a factorial design with all factors at two levels, each column of the design matrix (other than that corresponding to the general mean) consists of $n/2$ entries of 1 and $n/2$ entries of -1 . Therefore, there are only $n(n-1)\dots(n-n/2+1)/(n/2)!$ different columns possible and these can be divided into pairs of columns that can be transformed into each other by multiplication with -1 . An important analysis of fractional factorials is based on the half-normal plot (see **Half-Normal Plot** and [10]). In this analysis, the maximum of the absolute values of all estimated contrasts is compared to an estimate of the variance, see e.g. [11] for possible estimates of the variance and for critical values. Note that each fractional factorial design with n runs uses $n-1$ such columns. Therefore the

number of permutations that lead to different maximal contrasts gets relatively small. For instance, if $n = 4$, then there are only three different possible columns and each factorial design uses all of them. Hence the maximum contrast is constant – and the distribution of the maximum is clearly not normal. If $n = 8$, there are 35 different contrasts and each design uses 7. This implies that there are at most five different values of the maximum. So the normality assumption for the maximum contrast in an eight-run factorial design cannot be justified by randomization. For $n = 16$, however, the number of different randomization results gets sufficiently large: there are 6435 different contrasts and each design uses 15, which allows for 429 different values of the maximum. Kunert and Adekeye [12] did a simulation study, where they used a real data set from an experiment with a time trend and the permutation method introduced by Eden and Yates [7]. They demonstrate that the randomization distribution of the maximum contrast of a 16-run 2^{k-1} design fits well to the distribution that it should have under normality. They also show that the randomization of the run order can successfully deal with a time trend.

Factorial Designs, Resolution of

Introduction

The concept of design resolution was introduced by Box and Hunter in 1961 [1] in the context of two-level *fractional Factorial designs* (see **Fractional Factorial Designs**) of the type 2^{k-p} with the intent of defining a general index by which these designs could be easily ranked. The index, the resolution R , is very helpful to users at the stage of design selection. In fact, maximum resolution designs are the most commonly adopted in practice. We briefly recall some notions for an easier understanding of resolution. A 2^{k-p} design allows us to study the effects of k two-level factors on the response by running only a 2^{-p} fraction of the corresponding full factorial design. However the reduction in size (2^{k-p} runs instead of 2^k) is trade-off against a reduction in information. The latter is due to *aliasing of effects* (see **Aliasing in Fractional Designs**), meaning that the 2^k effects (*main effects* (see **Main Effects**) plus *interactions* (see **Interactions**) up to order k plus the constant effect) are split into 2^{k-p} groups containing 2^p fully undistinguishable effects (effects in each group are estimated by the same linear combination of the observations). These groups form the aliasing pattern of the design. Thus an individual effect can be estimated only if the effects with which it is aliased are sufficiently smaller than it. Hence, if we rely on the empirical principle that lower order effects are more likely to be important than higher-order effects (hierarchical ordering principle), a good fraction is one that protects low order effects – typically main-effects and two-factor interactions – by aliasing them with higher-order effects. Roughly speaking, resolution measures the degree to which this desirable aliasing pattern is realized by the design. Following Wu and Chen [2] it is instructive to call a main-effect or a two-factor interaction *clear* if it is not aliased with any main-effect or any two-factor interaction and *strongly clear* if it is also not aliased with any three-factor interaction.

Definition, Rationales, and Use of Resolution

A design is of resolution R if any effect containing q factors is not aliased with any other effect containing fewer than $R - q$ factors. R is denoted by a capital Roman numeral, usually appended as a subscript to the design indication, e.g., 2_{IV}^{4-1} designates a resolution IV half-fraction of the full factorial with four factors. We now focus on designs of resolution III, IV, and V, the most widespread in practice.

Resolution III designs

Main effects are not aliased with one another but some main effects are aliased with two-factor interactions. Thus some main effects and some two-factor interactions are not clear.

Resolution IV designs

Main effects are not aliased with one another or with any two-factor interaction. Some main effects are aliased with three-factor interactions and some two-factor interactions are aliased with other two-factor interactions. Thus all main effects are clear and some two-factor interactions are not clear.

Resolution V designs

Main-effects and two-factor interactions are not aliased with any other main-effects or two-factor interactions. Some main effects are aliased with four-factor interactions and some two-factor interactions are aliased with three-factor interactions. Thus all main effects are strongly clear and all two-factor interactions are clear.

Therefore, while resolution III designs are used in practice primarily for screening purposes (see **Screening Designs**), i.e., to rule out inactive factors from subsequent experiments, resolution IV and V designs may also be used for response prediction. In fact, assuming that main-effects and two-factor interactions are sufficiently larger than higher-order interactions, resolution IV designs capture the linear behavior in the factors of the response while resolution V designs also capture the interactive part of the possible nonlinear behavior in the factors. These are guidelines for users to choose a design resolution consistent with the objective of the experimentation. In practice an efficient approach to knowledge building by designed experiments is

the sequential one [3]. It advises to spend the total experimentation budget on a series of related experiments, each one designed adaptively, i.e., based on information drawn from the previous ones. A typical sequence of experiments would foresee an initial screening phase where highly fractionated factorials rule out inactive factors. This would be followed by higher resolution fractions allowing for the identification of a good operating region in the factor space. Finally, an optimum factor setting would be obtained by fitting a quadratic model to data coming from the efficient three-level designs recommended by the response surface methodology (RSM, *see Response Surface Methodology*). Thus the increase of resolution is a guiding mechanism in *sequential experimentation* (*see Sequential Experimentation*). A useful result in this context is that, after running a resolution III fractional design, main effects can be easily de-aliased from two-factor interactions. In fact, if the same design is run again but switching the signs of levels in all factor columns (*foldover* technique, *see Foldover Designs*), the ensemble of the two designs is a resolution IV design.

It is also worth mentioning a group of resolution III designs that are particularly efficient in terms of run size. If the number of factors k is one less than a power of 2, a resolution III design with only $k + 1$ runs is available. Thus one may study the main effects of seven factors with an 8-run 2^{7-4} , or the main effects of 15 factors with a 16-run 2^{15-11} , and so on. These designs are also a subset of the *Plackett–Burman designs* (*see Plackett–Burman Designs*).

Interestingly, the importance of resolution can be appreciated from another viewpoint. An appealing property of fractional designs is that when a design of resolution R is projected in any $R - 1$ (or less) factors, a full factorial design is generated in those factors (*see Projectivity in Experimental Designs*). (Note that the projection of the design in a subset of the original factors is another design obtained by omitting in the original design the columns of the factors in the complementary subset.) Therefore, if one believes that not more than $R - 1$ of k investigated factors are active (but without knowing which!) a design of resolution R is a good choice: if the conjecture is true, all the effects of the active factors can be estimated without aliasing.

Determination of Resolution

An easy way to determine the resolution of a two-level fractional factorial exploits the fact that it is equal to the number of letters of the shortest word in the *complete defining relation* of the design (sometimes referred to as the *defining contrast subgroup*). The latter is an equation expressing the aliasing in the group of 2^p effects whose contrast column is all 1's. The equation contains only p independent words called *generators of the design* (*see Fractional Factorial Designs*). The constant effect, denoted by I , is referenced as the first in the group but it does not count as a word for determining the resolution. As an example consider the 2^{8-2} design with generators $ABCD$ and $EFHG$. As the complete defining relation $I = ABCD = EFGH = ABCDEFGH$ has two words of length 4 and one word of length 8 the design is of resolution IV. However, the highest possible resolution for a 2^{8-2} design is V. It is obtained by choosing $ABCDG$ and $ABEFH$ as generators. This gives the complete defining relation $I = ABCDG = ABEFH = CDEFGH$ with two words of length 5 and one word of length 6. A notable consequence of the operational definition of resolution is that the maximum resolution of half-fractions (2^{k-1} designs) is equal to the number of factors, k . In fact, because these designs have only one generator, the maximum resolution is simply obtained by choosing the contrast of the highest order interaction as the generator. As an example, the maximum resolution for a 16-run 2^{5-1} design is V and is obtained by choosing the generator $ABCDE$ (and defining relation $I = ABCDE$).

Other Criteria for Design Selection

Resolution is not the only criterion used to select a 2^{k-p} design. A first instance occurs when, for given k and p , there is more than one design of maximum resolution. In such cases the subcriterion of *minimum aberration* (*see Minimum Aberration*) is usually applied. It amounts to choosing the maximum resolution design with the smallest number of words with minimum length. This ensures that the design has the minimum number of main effects aliased with interactions of order $R - 1$, the minimum number of two-factor interactions aliased with interactions of order $R - 2$, and so

on [4]. Consider the three 32-run 2^{7-2} designs defined by the complete relations $I = ABCF = ABDG = CDFG$, $I = ABCF = ADEG = BCDEFG$, and $I = ABCF = ABDEG = CDEFG$ respectively. As the minimum word length in each relation is four, the three designs are of resolution IV, the highest resolution for a 2^{7-2} . Therefore, while main effects are all clear, two-factor interactions are not. However, the third design is also of minimum aberration as its defining relation has only one word of minimum length, while the first design has three and the second has two. This means that the third design has a higher number of clear two-factor interactions than the first and the second design have. In fact, it has 15 clear two-factor interactions out of 21 (all but the three aliased pairs $AB = CF$, $AC = BF$, and $AF = BC$), while the second design has 9 and the first only 6. It may still be that a design with maximum resolution and minimum aberration does not maximize the number of clear effects. For such circumstances Chen *et al.* [5] proposed the number of clear effects as an alternative criterion. A simple illustration refers to the class of 2^{6-2} designs. The maximum resolution design in this class (complete relation $I = ABCE = ABDF = CDEF$) has resolution IV, and only the six main effects are clear. Yet, the 2_{III}^{6-2} design with generators ABE and $ACDF$ (complete relation $I = ABE = ACDF = BCDEF$) is only of resolution III but has nine clear effects, three main effects (C , DF) and six two-factor interactions (BC , BD , BF , CE , DE , EF). Finally, there are cases when we are interested in protecting specific effects which we believe are more important in the application at hand. This usually requires a close scrutiny of possible aliasing patterns since turnkey solutions are not available. One exception is when it is important to estimate clearly the main-effect and all the two-factor interactions involving one particular factor. In this circumstance a simple rule is to choose a design whose generators do not involve that factor. One example is the 16-run 2_{III}^{6-2} design whose generators ABE and ACF do not include factor D . Although the design is of resolution III, one can easily show from the complete defining relation ($I = ABE = ACF = BCEF$) that the **main effect** of factor D is strongly clear and the five two-factor interactions involving D are clear. This is not so for the maximum resolution 2_{IV}^{6-2} design seen before. For more details refer to [6, Section 4.5, p.177]. Tables containing maximum resolution (with minimum aberration) designs can be

found in [7, Section 8–4, pp. 328–330], while [6, Appendix 4A, pp. 193–199] provides more comprehensive tables for $k-p$ in the range 3–6 and k up to 32, where designs maximizing the number of clear effects are also reported.

Resolution may also apply to fractions of three (or higher) level factorial designs. Readers interested in the extension of resolution in those settings may refer to [6, Sections 5.4 and 5.6].

Sample-Size Determination in Experimental Designs

Introduction

Sample-size problems deal with the general issue of collecting enough data to achieve a stated goal. The importance of **sample size** varies considerably, depending on context. There are several possible criteria for sample size, the two most popular being specifying the width of a **confidence interval** or the **power** of a test with a specified effect size. Those are the main areas of emphasis in this article.

With either approach, it is usually necessary to have prior information concerning one or more variances; thus, one generally needs a pilot study or historical data where measurements are made using the same procedures, instrumentation, and comparable materials or subjects. Conversely, it can be argued that in the absence of such historical pilot data, one should not expect to be in a position to plan a definitive study, and hence sample size is not a very important issue. Indeed, if one's measurements and procedures have not been tested, there is much that can go wrong besides having an inadequate sample size. A pilot study need not be of the same design as the study being planned.

Useful general references for sample size include [1, 2], and [3]. A particularly useful recent reference for the power approach is [4]; while it emphasizes clinical experiments, it covers a great deal of common ground with other areas of application. It also contains a good discussion on study objectives (e.g., testing for significance, noninferiority, equivalence) that deserves the attention of readers in all areas of research.

The treatment in this article emphasizes frequentist methods for **estimation** and **testing**. Good sample-size software is now widely available, whereas many formulas are only rough approximations and apply to very limited – and usually oversimplistic – scenarios. For these reasons, this article emphasizes the use of software. Several standard statistical packages (including Statistical Analysis System (SAS) and *Minitab*) offer good sample-size capabilities; there are also commercial programs specifically for sample

size, such as *nQuery Advisor* and *NCSS-PASS*, and on-line power and sample-size calculators such as *Piface* [5].

Simple Illustration

Suppose that we plan to collect paired data on the percentage of solids at two locations in a pipeline used to transport a liquid. We believe that the paired differences are approximately normal, and we plan to use a paired *t* procedure to analyze the data. We have past data (see [6]) on another similar pipeline on locations about the same distance apart, and those data suggest that the standard deviation σ of the paired differences is about 0.14%.

The percentages of solids are quite small, but somewhat critical. After discussing the matter with the research team, it is decided that we would like to know if there is a 0.10% or greater difference in the means at the two locations. How much data are required?

One traditional approach is that of specifying the width or half-width of a **confidence interval**. In this case, the 95% confidence interval half-width for a sample of n pairs will be $t_{0.025, n-1}s/\sqrt{n}$, where s is the sample standard deviation, and $t_{0.025, n-1}$ is the critical value for a 0.025 tail on the *t* distribution with $n - 1$ **degrees of freedom** (df). If we want the half-width to be 0.10 or smaller, then by solving for n , we obtain $n \geq (t_{0.025, n-1}s/0.10)^2$. We estimate that s will be about 0.14; the *t* critical value depends on n , but only weakly if n is moderate or large. Thus, if we guess that n will be about 30, say, then we obtain $n \geq (2.045 \times 0.14/0.10)^2 \approx 8.2$. Thus, perhaps $n = 9$ is adequate; but this estimate is based on 29 df. Correcting the degrees of freedom to $9 - 1 = 8$, we get $n \geq (2.306 \times 0.14/0.10)^2 \approx 10.4$. Correcting yet again to 10 df, we obtain $n \geq 9.7$. It appears that $n = 10$ will be adequate for obtaining a confidence interval of the desired width.

Note that even in this simple situation, there is a certain amount of handwaving when we substitute 0.14 for a future value of s , plus some iterating on the degrees of freedom. Our previous data may have under- or overestimated σ ; in addition, the future value of s in the planned experiment may be larger or smaller than 0.14. We may want to take such considerations into account; for example, instead of using the point estimate of 0.14 for σ , perhaps an

2 Sample-Size Determination in Experimental Designs

upper confidence limit for σ would be better to ensure that we collect enough data. Such decisions are subjective and based largely on how important it is in this particular case to get the sample size right.

The other traditional approach is to choose n so as to achieve a specified *power* of the t -test when there is a 0.10% difference between the means. The calculations here are more complex, and it is best to use software to solve the problem. Typically, we specify a power of 0.80 or 0.90. The output from SAS (using PROC POWER) is shown in Table 1. For a power of 0.80, we need $n = 18$. To achieve a power of 0.90, we need a lot more data ($n = 23$): once the power exceeds 0.7 or 0.8, there is a large cost for a small increase in power. Note also that the sample size for a power of 0.50 is $n = 10$, the same as we obtained for the confidence interval approach. This is approximately true in general: the sample size for 50% power in a two-sided test is about the same as that for a $(1 - \alpha)$ confidence interval of the same half-width.

SAS also provides for a powerlike concept in confidence intervals – that of specifying the probability that the interval is no wider than a specified value; or the conditional probability thereof, given that the interval contains the actual parameter value (see [7]). Unlike the previous confidence interval approach, this takes into account the variation in s . The output is shown in Table 2. Again, we obtain $n = 10$ for a “power” of 0.50. We need a somewhat larger value of n as the requirements increase; and with $n = 15$, there is a very good (conditional) chance that the half-width of the confidence interval will be 0.10 or

less. When the focus of a planned study is on estimation, this approach deserves more attention than it currently gets.

When is Sample Size Important?

An *observational study* or *experiment* is considered underpowered when there is a low chance of obtaining statistical significance for an effect of such magnitude as to be considered important scientifically; and it is overpowered when a scientifically unimportant effect would still be statistically significant. Power increases as sample size increases, so one can control the power of a study by choosing the sample size.

It is always important to avoid overpowering a study – that is, we should not collect too much data. At best, it is wasteful of resources; and in cases where human or animal subjects are involved, too much data may translate into too many subjects being exposed to a potentially harmful treatment, or being denied a beneficial one.

Having an adequate sample size is most important when a definitive study is planned and there are substantial costs (in money or time or otherwise) involved in collecting more data later. For example, in a situation where it takes a long time to carry out an experiment, it also takes a long time to know whether there are any clear conclusions, and yet more time to run a follow-up experiment to establish results at greater precision.

Table 1 SAS PROC POWER output for the power approach in the paired t -test

Distribution	Normal

3	0.9	0.942	15

Sample size is least important in pilot studies, where the emphasis is less on obtaining definitive scientific results and more on establishing that one's procedures work and estimating one or more error variances for a later, more definitive study. Adequacy of sample size is also relatively unimportant in a situation where *sequential experimentation* is practical – where additional data can be collected readily as needed. However, even then, one must not underestimate administrative barriers – work shifts, funding, availability of personnel, and so on – that might significantly impede the collection of more data.

Almost any course of investigation begins with at least one stage – piloting – where sample size is relatively unimportant, and proceeds to one or more final stages where sample size is relatively important. The early stage(s) establishes the procedures and knowledge needed to assess the sample-size requirements for the later, definitive stage(s). This discipline of piloting and planning is necessary for a successful investigation, and it is a mistake to try to cut it short.

Eliciting Effect Size

One of the toughest hurdles one faces in addressing a sample-size problem is the specification of effect size (or confidence interval half-width). This needs to be based on scientific rather than statistical concerns; but usually the statistician needs to facilitate the conversation on this issue. If the question is asked naively (e.g., “What difference would you consider scientifically important?”) the answer is likely to be equally naive (e.g., “any difference at all” or “you tell me”). A slightly oblique approach is more likely to be successful; for example, ask “How different can these two groups be, and still be considered the same in a practical sense?”

Because effect size is such a daunting question, people tend to seek an easy way out – for example, using a predefined “large”, “medium”, or “small” effect size (see [8]). These “T-shirt” effect sizes are expressed in standard deviation units and are based on surveys of published research in the social sciences. This seems to be a way of following the norms of existing research; however, thinking about this carefully, it becomes clear that choosing a “medium” effect size will always yield the same sample size as a medium-sized study in the social science literature – no calculations are needed. Moreover, this

simpleminded approach yields the same sample size regardless of variation in the instrumentation used to obtain measurements – whereas intuitively, the more precise the measurements, the less data are needed. If the study is important, so is its planning, and for that reason, the focus of the discussion should be on the actual scale of measurement (or some transformation thereof), and the question of effect size should be considered seriously.

An alternative way to specify effect size is through a set of exemplary data—an artificial data set that contains no variation but exhibits a non-null case that would be considered to be of minimal scientific significance. A simple example is that of testing a six-sided die for fairness. A fair die has a probability of $1/6 \approx 0.1667$ for each outcome. An exemplary unfair die might have probabilities 0.15, 0.15, 0.15, 0.15, 0.20, 0.20, so that a corresponding exemplary data set would have proportional frequencies – say 3, 3, 3, 3, 4, 4. The χ^2 goodness-of-fit statistic (see **Statistical Methods for Counts, Rates, and Proportions**) for these 20 exemplary observations is 0.4, and it turns out that the noncentrality parameter λ of the χ^2 statistic based on n observations is proportional: $\lambda = (0.4/20)n$. The Piface user interface is displayed in Figure 1, where we find that 578 die tosses are required to establish the exemplary die to be unfair, with a power of 0.75 and a **significance level** of 0.05.

Using Pilot Data

When the planned study involves measurement data, one must have estimates of one or more error variances in order to determine sample size. Accordingly, one must either have an existing data set for a similar situation or conduct a pilot study to estimate these variances. A pilot study can be beneficial for other reasons, such as checking that the planned experimental procedures actually work as anticipated.

The pilot study need not be of the same design as the planned study. The only requirement is that it should estimate the required variances. However, hidden sources of variation must be carefully considered to make sure that a single variance in one study is not the sum of several variances in the other. For example, suppose a pilot study entails one measurement of hardness on each of several ingots of steel, while the planned study involves several hardness measurements on the same ingot. The pilot study

Figure 1 Piface interface for a χ^2 test

estimates the sum of the between- and within-ingot variances, whereas the planned study considers these variances separately.

One question that comes up is to what extent the results of the pilot study should affect the planning of the main study. For example, the pilot will yield an estimate of the effect of interest – should this estimate be used in sample-size planning? Strictly speaking, the answer is “no”, in deference to the effect size we have so carefully elicited based on scientific concerns. However, if the effect size observed in the pilot is much greater than the scientifically important one, it suggests that the main study can be downsized, thus saving cost and reducing exposure of subjects. Accordingly, it is reasonable for the sample-size planning to be based on a lower confidence bound on the effect size, provided that this bound is at least as large as the scientifically important effect size.

Multifactor Example

An experiment is to be conducted on a semiconductor manufacturing process; the response variable of interest is oxide thickness (in Angstroms, denoted Å). The plan for the experiment is to be a *split-plot*

design: silicon wafers will be processed in lots of four wafers each, each wafer being randomly assigned to one of four treatments. Subsequently, oxide thickness will be measured at each of five fixed sites on each wafer (the split-wafer part of the design). The mixed model to be used for the analysis has fixed terms for treatment, site, and treatment $\times$ site, and random effects for lot, lot $\times$ treatment, and residual error.

The sample-size question is simply how many lots should be included in the experiment. But it is a complicated question because three fixed effects came under discussion in the effect-size elicitation process. First, it was decided that we need to detect a difference of ± 10 Å between any two treatments. Second, we want to be able to detect a difference of ± 5 Å between any two sites; and finally, we want to detect a difference of ± 15 Å between any two treatment $\times$ site combinations (see **Interactions**). These effect-size choices are based partly on considerations of the fact that whole-wafer comparisons are less accurate than split-wafer comparisons.

We have past data on the same process, but with a different experimental design – a nested layout with eight lots, three random wafers in each lot, and three random sites in each wafer. The data are given in Littell *et al.* [9], and the analysis provides variance-component estimates of 129.9 for lots, 35.87 for wafers nested in lots, and 12.57 for sites nested in wafers. In the planned experiment, the random effect of lot $\times$ treatment (i.e., the whole-wafer error) corresponds exactly to wafer-to-wafer variations in the pilot data, and so we estimate its standard deviation to be $\sqrt{35.87} \approx 6.0$. The standard deviation of $\sqrt{12.57} \approx 3.5$ for sites within wafers in the pilot data does not correspond to a random effect in the planned study; however, since it includes variations of randomly selected sites, it is reasonable to believe that it overestimates the residual variation for the planned experiment; so using it will provide a conservative assessment for sample-size purposes.

Figure 2 shows the related Piface dialog. The various sample sizes are in the left panel and the standard deviations are in the center panel. In the right panel, we select what effect to study, specify the effect size, and observe the power. In the figure, it is set to study the treatment $\times$ site comparisons, with a restriction that we are comparing two treatments on the same site using the honestly significant difference (HSD)

Figure 2 Piface dialog for the split-plot example

procedure. When there are 10 lots in the experiment, the power is quite high for this setting.

There are several other tests that need to be studied, and we need to consider each of them and look for the worst case. Using other settings that are not shown in Figure 2 (all with 10 lots and the HSD method), we find that the power is nearly 1 when comparing two sites with the same treatment (a split-plot comparison has better resolution); the power drops to about 0.84 when no restrictions are placed on the interaction comparisons (because now we have 20 means in the HSD procedure). For the treatment comparison, the power is about 0.80 when the difference is 10 (as per our specifications); and for the site comparisons, the power is nearly 1 when the difference between two site means is 5. Thus, the worst case is the treatment comparison, and we have found that 10 lots is adequate to achieve 80% power for that comparison, using Tukey's HSD.

Allocation

The allocation of sample sizes among several groups is an issue related to sample size. In settings where the variances are equal and all groups are to be compared on an equal basis, a balanced allocation is best. However, if the primary goal is to compare each of k treatment means with a control mean, it

can be shown that for a given total sample size, the **standard error** of the treatment-minus-control comparisons is minimized when the sample size of the control group is $\sqrt{k}$ times the sample size of each treatment group, assuming equal variances. If the variances are unequal and if all means are to be compared symmetrically, the best allocation is in proportion to the standard deviations. These rules can be combined; for example, if we have two treatments to be compared with a control, and the respective standard deviations are σ_{t_1} , σ_{t_2} , and σ_c , the best allocation of sample size is in proportion to σ_{t_1} , σ_{t_2} , and $\sqrt{2}\sigma_c$.

Cost considerations can also drive allocation of sample size. For example, in a nested experiment we may incur a certain cost each time we change to a new batch of raw material, and we have the option of running several tests on each batch at some other cost per test. One can use appropriate optimization techniques to find the number of batches and tests per batch to maximize the power of some test, subject to a constraint on the total cost of the experiment.

Planning a Pilot Study

As explained earlier, it is important in most sample-size problems to have good estimates of one or more standard deviations. That puts us in a circular

situation, in that pilot estimates of standard deviations are themselves subject to sampling error. What then is the required sample size for a pilot study?

One way to address this is to note that the principal risk we face here is that of underestimating the needed sample size. Suppose that if the true error standard deviation σ were known, we could determine that a sample size n is required for our study. The requirements of the pilot study might then be stated as follows: We are willing to take a risk γ of obtaining a sample size of only $\tau \cdot n$, where $\gamma < 1$ and $\tau < 1$ are specified.

In most settings, the required sample size is roughly proportional to σ^2 . Suppose that S^2 is an estimator of σ^2 based on a pilot study. Under a normal-theory model, $\nu S^2/\sigma^2$ has a χ^2 distribution with ν degrees of freedom. We require that $P(S^2/\sigma^2 < \tau) \leq \gamma$, and thus that $P(Y < \nu\tau) \leq \gamma$, where Y has a χ^2_ν distribution. Using this result we can find, for example, that an estimator S^2 having $\nu = 78$ df is sufficient to achieve a risk of $\gamma = 0.10$ of obtaining a sample size only 80% of what is needed ($\tau = 0.8$). Reducing τ to 0.7 reduces the needed degrees of freedom to 33, for the same risk. Piface provides a simple user interface for this method.

We can also use these results to obtain a “fudge factor” to adjust a sample-size calculation. For example, suppose that, based on a variance estimate having 33 df, we calculate a sample size of $n^* = 75$ is needed to achieve certain requirements. If we conduct the study instead with a sample size of $n^{**} = n^*/0.7 \approx 107$, then there is only a 10% chance that this sample size is too small to meet the stated requirements of the study (see the example in the preceding paragraph).

Conclusions

Sample-size determination starts with scientific rather than statistical considerations: we must evaluate the goals of a planned study in scientific terms. In addition, a definitive study can rarely be planned without first collecting pilot data. In many sample-size problems such as the multifactor example in this article, there are multiple targets to consider. New

software makes it increasingly easy to deal with all of these complexities.

The power approach to sample size becomes confounded somewhat by some other uses (and abuses) of power calculations. For instance, some researchers attempt to use power calculations as an aid in data analysis. This is generally a mistake, unless it is done prospectively. The reader is referred to [10] for a discussion of such matters.

Screening Designs

Introduction

In the planning stages of any experimental study, a number of critical questions need to be asked. Among these are questions regarding the choice of experimental factors and factor levels to include in the study. A factor is a variable that is studied in the experiment and is believed to potentially have an effect on the response. The values of the factor at which experimental runs are conducted are called the *levels* of the factor. The actual list of factors to initially include in a study usually arises as the result of discussions with scientists or engineers most familiar with the process being studied. When the list is long, it is often the case that a relatively small subset of the factors actually has an influential effect on the response, and it is important, in the early stages of the experimental study, to identify those influential factors. This is the purpose of screening experiments. Once the influential variables have been identified, a more elaborate experimental study is usually conducted to develop a more detailed mathematical model which can be used to further describe relationships between the influential variables and the response.

A factor to be included in a study may be either quantitative or qualitative. Quantitative factors such as time or temperature can assume all values on a continuous scale. Qualitative factors such as different machine types or different crop varieties have levels which can assume only discrete values and typically cannot be rank ordered. In screening experiments, most factors are tested at no more than three levels and more typically occur at two levels. For a quantitative factor, two levels allow for the detection of a linear effect on the response. When it is suspected that a quantitative factor may affect the response nonlinearly, three or more levels of the factor can be chosen and used to detect curvature in the factor effect. There is usually much less freedom in the selection of levels for a qualitative factor as these levels are determined by the qualitative nature of the particular factor. For example, if four different machine types are being considered in an industrial experiment, then the qualitative factor, machine type, would have four levels.

The most popular screening experiments in use today are factorial experiments (*see* **Factorial Experiments**). A factorial experiment is one whose treatments consist of different combinations of experimental factor levels. In the rest of this article, the use of factorial screening designs to identify influential factors in the early stages of an experimental study is discussed.

Notation and Model

In this article, experimental situations are considered in which m factors are to be studied using a factorial experiment with N runs. We use d to denote a design which can be used in such a situation and interchangeably represent d by $X_d = (x_{d1}, \dots, x_{dm}) = (x_{dij})$, which is an $N \times m$ matrix whose i th row corresponds to run i and j th column corresponds to factor j . If factor j has s_j levels, then the entries in column j of X_d will consist of symbols $1, 2, \dots, s_j$ with $x_{dij} = t \in \{1, 2, \dots, s_j\}$, if factor j occurs at level t in run i . A useful model for analyzing the data from a given design d is

$$Y = \beta_0 \mathbf{1}_N + \sum_{i=1}^m X_{di} \beta_i + \epsilon \quad (1)$$

where Y is an $N \times 1$ vector of observations, β_0 is the overall mean effect, $\mathbf{1}_N$ is an $N \times 1$ vector of 1's, X_{di} is an $N \times (s_i - 1)$ matrix corresponding to factor i having s_i levels, β_i is an associated set of main effect (*see* **Main Effects**) parameters, and ϵ is a vector of random error terms whose entries are assumed to be uncorrelated with mean zero and constant variance σ^2 . The actual entries of X_{di} usually depend upon whether factor i is a quantitative or qualitative factor. If factor i is a quantitative factor with s_i levels, the entries of X_{di} are usually coded (using orthogonal polynomials) so that all polynomial effects up through degree $s_i - 1$ can be estimated orthogonally to one another. For example, if factor i has three equally spaced levels all occurring in $N/3$ runs, then X_{di} has two columns with entries $-1, 0, 1$ and $1, -2, 1$ depending on whether factor i occurs at its low, middle, or high levels. If factor i is a qualitative factor with s_i levels, then the entries of X_{di} can be coded in several different ways. We shall assume for convenience that the average effect among levels of factor i is zero which implies one parameterization,

where column j of X_{di} corresponding to level j , $j = 1, \dots, s_i - 1$, has entries 1 if factor i occurs at level j , -1 if factor i occurs at level s_i , and 0 otherwise. The actual parameters in model (1) are typically estimated using the method of **least squares**.

We note that the model given in equation (1) only allows a main-effects analysis for a given set of observations. However, additional columns can be added to model (1) corresponding to interaction parameters (see **Interactions**) by taking component-wise (Hadamard) products between the appropriate columns in model (1) involved in the interaction. We shall say that a design d is saturated if $\sum_{i=1}^m (s_i - 1) + 1 = N$. For saturated designs, only main-effect parameters can be estimated. In many screening experiments, the designs used are either saturated or nearly saturated and leave few **degrees of freedom** for estimating error. In these situations, analysis of the data to find significant main effects in model (1) usually depends upon the form of the matrices X_{di} in model (1). If the columns of all the X_{di} are orthogonal to one another and the corresponding parameter estimates can be assumed to be normal random variables with equal variances, then graphical methods such as half-normal plots (see **Half-Normal Plot**) can be used to identify significant effects. However, because the use of graphical methods is somewhat subjective in nature, other more objective statistical methods have been developed, for example, see Hamada and Balakrishnan [1] for a good discussion of methods available such as Lenth's method (see **Lenth's Method for the Analysis of Unreplicated Experiments**). When the columns of the X_{di} in model (1) are nonorthogonal or are orthogonal but the corresponding parameter estimates do not satisfy the assumptions appropriate for the use of graphical or other available methods, regression analysis and variable selection techniques can be used to identify significant effects.

Basic Principles for Screening Experiments

With regard to the usage of factorial designs as screening experiments, there are several principles which are often of use in both the choice of an experimental design and in the analysis of data obtained from a given experiment. These are the principles of hierarchical ordering, effect sparsity, and effect heredity. The general validity of these

principles has been established over time and a great deal of empirical observation.

The principle of hierarchical ordering says that lower-order interactions are more likely to be important than higher-order interactions, and it implies that main effects are more likely to be important than two-factor interactions, which are more likely to be important than three-factor interactions, and so on. This principle often leads to the additional assumption used in practice that in models such as equation (1) which might include interactions, three-factor and higher-order interactions are negligible. This latter assumption concerning three-factor and higher-order interactions is further justified through empirical evidence and the fact that three-factor and higher-order interactions are difficult to interpret.

The principle of effect sparsity says that the number of influential effects in a factorial experiment is likely to be small and has been observed to be the case in many factorial experiments. This principle is one reason why factorial screening experiments often prove successful in the identification of significant factors on a response.

The last principle, that of effect heredity, says that in order for an interaction to be significant, at least one of the factors involved in the interaction should be significant. This latter principle is of use in the determination of models which make physical sense, since in most experiments it is difficult to envision a significant interaction without at least one of the involved factors being significant. It is also of use in the development of follow-up design strategies.

Two-Level Orthogonal Designs

In this section, we consider two-level designs which allow for the orthogonal **estimation** of all main effects as these are the types of designs which are most often used as screening experiments. For these designs, the matrices X_{di} , $i = 1, \dots, m$ in model (1) consist of a single column with entries -1 or 1 depending on whether factor i occurs at a low or a high level in a given experimental run. The actual levels of a quantitative factor usually occur at different values but are coded so as to assume values -1 or $+1$ in equation (1). For qualitative factors, the same coding is used, with one of the factor levels being declared to be the "high" level.

Complete 2^m Designs

A complete 2^m design d is a design containing runs at all possible 2^m treatments that can be constructed from all possible level combinations of the m factors. The statistical analysis of such designs under a model such as equation (1) (with interactions included) typically involves the use of half-normal plots or standard analysis of variance (see **Analysis of Variance**) techniques.

Advantages

The primary advantage of complete 2^m designs is that they allow for the orthogonal estimation of all main effects and interactions between experimental factors (when such terms are included in the model). This lets an experimenter gain a greater understanding of how the response variable is related to the experimental factors being studied.

Disadvantages

Because 2^m grows exponentially as m increases, the number of runs required for a complete 2^m design becomes large quickly. For this reason, complete 2^m designs are not used much as screening designs unless m is relatively small ($m \leq 5$).

Regular 2^{m-k} Fractional Factorials (FF)

To handle experimental situations where m is relatively large and complete 2^m designs are not practical, designs called *regular 2^{m-k} fractional factorial (FF) designs* (see **Fractional Factorial Designs**) are often used. Regular 2^{m-k} FF designs are constructed using defining relations groups. In constructing a 2^{m-k} FF design d , the m factors consist of two types. There are $m - k$ “basic” factors, assumed to be those factors labeled $1, \dots, m - k$, such that the 2^{m-k} design is a complete factorial when considered just in terms of the basic factors. The other factors, labeled $m - k + 1, \dots, m$, are called *added factors* and are obtained by associating each added factor with some interaction in the basic factors. Each matrix X_{di} , $i = m - k + 1, \dots, m$, corresponding to an added factor and consisting of a single column in model (1) is obtained by taking the component-wise product of the single column matrices corresponding to the basic factors in its associated interaction. By combining each added factor label with those of the basic factors in their associated interaction, we obtain

the treatment defining effect words of the design. All possible products among the treatment defining words (according to the rule, if a factor label appears an even number of times in the product, it is deleted, whereas if it appears an odd number of times, it is kept) form an algebraic group called the *treatment defining relations group* which we denote by $G_t(d)$. We note that in any regular 2^{m-k} FF design d , the columns corresponding to any two distinct factorial effects (when included in model (1)) have euclidean inner product $\pm N$ or 0. When the columns corresponding to two factorial effects have inner product of $\pm N$, we say those effects are totally aliased (see **Aliasing in Fractional Designs**) or confounded. To find the **aliasing** set of a given factorial effect, that is, those factor effects that are totally confounded with it in d , simply multiply all words in $G_t(d)$ by the factorial effect using the multiplication rule for $G_t(d)$ given above.

Example 1: To study $m = 5$ factors in eight runs, one would use a regular 2^{5-2} design d . In such a design, factors 1, 2, and 3 are the basic factors and the levels of the two added factors 4 and 5 can be defined in terms of the basic two-factor interactions by $4 = 12$ and $5 = 13$. In d , the defining effect words are 124 and 135 and $G_t(d) = \{I, 124, 135, 124 \cdot 135 = 2345\}$, where I is the identity element of the group. The aliasing set for an interaction such as 134 is obtained by multiplying all words in $G_t(d)$ by 134 to get $\{134, 23, 45, 125\}$.

For more information on construction and a listing of good regular 2^{m-k} FF designs, the reader is referred to Chen *et al.* [2].

With regard to the usage of regular 2^{m-k} FF designs as screening experiments, they have certain advantages and disadvantages that should be kept in mind.

Advantages over 2^m designs

1. Economy of run size. In a 2^{m-k} regular FF design, there are $r = m - k$ basic factors and $N = 2^{m-k}$ runs. Such designs can accommodate up to $N - 1$ factors including the r basic factors and $2^r - r - 1$ added factors, one added factor for each interaction in the basic factors.
2. The analysis of 2^{m-k} designs is simple and well understood. All main effects can be estimated orthogonally and hence efficiently. The actual identification of significant effects in a

4 Screening Designs

given regular 2^{m-k} FF design is often accomplished through the use of half-normal plots or through the use of one of the more objective statistical methods discussed in Hamada and Balakrishnan [1].

3. The aliasing structure for such designs is simple, that is, factor effects are either totally confounded or orthogonal. This makes it easier to construct follow-up designs when aliased effects need to be broken out.
4. Many 2^{m-k} designs have desirable projection properties (see **Projectivity in Experimental Designs**). In particular, if a 2^{m-k} design has resolution R (see **Factorial Designs, Resolution of**), that is, the shortest word in $G_I(d)$ has exactly R letters in it, then any projection of the design onto $R - 1$ factors is a full factorial in the $R - 1$ factors. This fact can be used when analyzing the data from a 2^{m-k} design. For example, if only $R - 1$ of the factors from the original 2^{m-k} resolution R design are found to be significant, then all the interactions among the $R - 1$ factors can also be estimated without taking any additional observations because the projected design onto the $R - 1$ factors is a complete factorial.

Disadvantages

1. The number of runs for a 2^{m-k} design must be a power of 2. This limits their flexibility and availability as a viable option in many experimental settings.
2. The fact that effect estimates are either completely confounded or orthogonal that was cited in 3 above as an advantage can also be a disadvantage. Complete confounding of main effects and low-order interactions can sometimes cause difficulty in the identification of truly significant factor effects and require additional observations to dealias confounded effects. For example, suppose the estimating contrast for factor i , which is aliased with interaction $i_1 i_2$, is found to be significant. If neither factors i_1 nor i_2 are significant, then one can use the effect heredity principle to possibly conclude that the significant effect was due to the main effect of i . On the other hand, if one or both of factors i_1 or i_2 are significant, then it may be difficult to conclude whether the effect was due to the main effect of i or the interaction

$i_1 i_2$. In the latter case, additional observations may be needed to resolve the issue.

Comment Complete s^m and regular s^{m-k} , $s > 2$ FF designs can be constructed using defining relations along the lines given in this section for 2^m and regular 2^{m-k} designs. However, because regular s^{m-k} FF designs are not used as often for screening experiments, we shall not consider them here.

Nonregular Orthogonal FF Designs

The regular 2^{m-k} designs discussed in the section titled “Regular 2^{m-k} Fractional Factorials (FF)” are constructed using defining relations among factors. In these designs, any two factorial effects are either completely confounded or estimated orthogonally with all main effects being orthogonally estimable. FF designs that allow for the orthogonal estimation of all main effects but have some factorial effects that are neither orthogonal nor fully aliased are called *nonregular orthogonal FF designs*. In this section, we discuss a collection of nonregular orthogonal two-level FF designs which are sometimes useful in screening experiments.

Plackett and Burman (PB) [3] introduced a series of two-level orthogonal FF designs, where N is a multiple of 4 and $1 \leq m \leq N - 1$ (see **Plackett–Burman Designs**). If N is a power of 2, these designs contain the 2^m and the regular 2^{m-k} designs given earlier as special cases. A catalog of PB designs for $N = 4$ to $N = 100$ can be found online at www.research.att.com/~njas/oadir/index.html.

The constructions of PB designs are not based on well-defined defining relations groups, hence they have what is often referred to as a *complex aliasing structure*. Two-factorial effects are partially aliased in an N -run two-level design if the euclidean product between their corresponding columns in model (1) has absolute value between 0 and N . PB designs involve a great deal of partial aliasing between main effects and two-factor interactions as well as between pairs of two-factor interactions. For example, in the 12-run PB design involving 11 factors, every main effect is partially aliased with every two-factor interaction not involving itself. Thus every main effect in the 12-run PB design is aliased with 45 two-factor interactions. The complex alias structure associated with PB designs needs to be carefully

considered when such designs are used for screening as it can serve as both an advantage and disadvantage.

Advantages over regular 2^{m-k} FF designs

1. Economy of run size. For example, if between 8 and 11 two-level factors are to be included in a screening experiment, the smallest 2^{m-k} design that can be used contains 16 runs. On the other hand, a 12-run PB design can be used to accommodate between 8 and 11 factors and requires four fewer runs. Similar situations occur for number of factors between 16 and 27.
2. Estimates for all main effects are orthogonal and will be unbiased as long as all two-factor and higher-order interactions are negligible.
3. PB designs have a useful projection property which occurs as a result of their complex aliasing structures. For example, consider a 12-run PB design. It has been shown that any projection onto the columns associated with four or fewer factors has the property that all main effects and two-factor interactions among the four factors are estimable when higher-order interactions are negligible. Additional results for other numbers of factors and other PB designs have also been established [4]. Even though the estimates for main effects and interactions yielded in the associated projection models are not necessarily orthogonal, the projection models do allow for additional analysis of main effects and interactions without requiring additional observations.

Disadvantages

1. An assumption typically made when PB designs are used is that two-factor and higher-order interactions are negligible. When this assumption is valid, PB designs can be of great use as screening experiments. Even when this assumption is not completely valid but only a few two-factor interactions are nonnegligible, methods of analysis such as those described in the next section can successfully identify influential effects. However, when the assumption is violated and more than a few two-factor interactions are nonnegligible, problems of interpretation can arise. For example, because the complex aliasing structure of PB designs involves main effects being partially aliased with so many two-factor interactions, whenever a main effect contrast is determined to

be significant, it may be difficult to tell if the significant contrast is due to the associated factor or some combination of the partially aliased two-factor interactions. In such situations, complex aliasing can lead to the identification of experimental factors that are not truly influential as being influential and completely miss other influential factors. While the first situation is not as serious, failure to identify influential factors in a screening process can have serious consequences. Because of the ambiguity associated with main-effects estimates in PB designs, they are typically used only for screening.

Analysis of Designs with Complex Aliasing

In the section titled “Nonregular Orthogonal FF Designs”, screening designs were introduced that had many main effects partially aliased with two-factor interactions. When this partial aliasing is severe, the identification of influential main effects can be difficult. However, Hamada and Wu [5] suggested two analysis strategies for designs with complex aliasing, which can be successful when the principles of effect sparsity and effect heredity hold, for example, see the section titled “Notation and Model”, and the correlations between partially aliased effects are small to moderate. Their method 1 proceeds as follows:

- Step 1. For each factor, X_i , consider the variable X_i and all its two-factor interactions $X_i X_j$ with other factors. Use a stepwise regression procedure to identify significant effects from the candidate variables and denote the selected model by M_{X_i} . Repeat this for each of the factors and then choose the best model. Go to step 2.
- Step 2. Use a stepwise regression procedure to identify significant effects among the effects identified in the previous step as well as all the main effects. Go to step 3.
- Step 3. Using effect heredity, consider all variables consisting of the effects identified in step 2 and (ii) the two-factor interactions that have at least one member appearing among the main effects in (i). Also, consider (iii) interactions suggested by the experimenter. Use stepwise regression to identify significant effects among the effects in (i)–(iii). Go to step 4.

Step 4. Iterate between steps 2 and 3 until the model stops changing.

Advantages of method 1

1. The method of analysis suggested above provides a systematic method for analyzing data from designs with complex aliasing. When the conditions mentioned in the first paragraph hold, simulation studies and empirical evidence suggest that the method can be used successfully.

Disadvantages of method 1

1. When the method is used and the conditions cited do not hold, then the method can miss influential effects.
2. If more than a few two-factor interactions are partially aliased with main effects, the method may identify some incompatible models, that is, it may identify several models that explain the data equally well but contain different variables.

Method 2

Assume effect sparsity holds and that no meaningful model can have more than h effects. Search over all models that have no more than h effects (plus an intercept term) and satisfy the effect heredity principle. Choose the best model according to a sensible model selection criterion.

Advantages of method 2

1. It is computationally simple and easy to understand.
2. It provides a search over a greater number of models than does method 1.

Disadvantages of method 2

1. If h is large, the implementation of the method may not be computationally feasible.
2. The disadvantages cited for method 1 also hold for method 2.

Nonorthogonal Two-Level FF Designs

All of the designs given in the section titled “Two-Level Orthogonal Designs” allow for the orthogonal estimation of all main effects. However, other FF designs are available which can be used in screening experiments but where main effects are not all

orthogonal. In this section, we introduce three such sets of designs.

Model Robust FF (MRFF) Designs

Li and Nachtsheim [6] introduced a series of nonorthogonal two-level model robust fractional factorial (MRFF) designs having $N = 8, 12$, and 16 runs and m factors with m varying between 4 and 10. These designs are model robust in the sense that each design given allows for the estimation of all main effects and any combination or a large proportion of the combinations of up to g (or fewer) two-factor interactions, where g is specified by the user. These designs were computer generated and the reader is referred to Li and Nachtsheim [6] for their actual structure. The analysis of these designs and identification of significant effects is usually done through the use of regression and variable selection methods.

Advantages

1. The primary advantage of the MRFF designs described in this section is that they can be used to investigate both main effects and a small number of two-factor interactions. This provides an experimenter the opportunity to investigate model parameters in addition to main effects without collecting additional data in a follow-up experiment.

Disadvantages

1. The primary disadvantage of MRFF designs is that main effects are partially aliased with each other and with two-factor interactions, hence these designs have a complex aliasing structure. All problems associated with designs having complex aliasing thus hold for these designs also.

Resolution IV Nonorthogonal Two-Level FF Designs

In this section, we consider two-level designs which are similar in some respects to the resolution IV regular 2^{m-k} FF designs considered in the section titled “Regular 2^{m-k} Fractional Factorials (FF)”. An arbitrary two-level design d is said to have resolution III if it allows for the estimation of all main effects assuming that all interactions involving two or more factors are negligible, and it is said to have resolution IV if it allows for the estimation of all

main effects assuming all interactions involving three or more factors are negligible. One simple method of constructing resolution IV two-level designs is the “foldover method” (see **Foldover Designs**). In this section, the term *foldover design* is used to indicate a design $\tilde{d}$ which is obtained from an original design d by combining the runs in d with those mirror image runs that can be obtained by reversing the signs of all the factors in d . Thus if the original design d has m factors and N runs, the foldover design $\tilde{d}$ obtained from d has m factors and $2N$ runs. Margolin [7] showed that if d is a two-level FF design having resolution III, then the foldover design $\tilde{d}$ derived from d has resolution IV. Margolin discussed folding over minimal and efficient, nonorthogonal, two-level, resolution III designs to create resolution IV designs having m factors and $2m$ runs. These designs have been further discussed by Miller and Sitter [8, 9] who also recommended a method of analysis based on the techniques of Hamada and Wu [5]. The reader is referred to Miller and Sitter [8, 9] for details.

Advantages

1. The estimates for main effects in a resolution IV design are not aliased with any two-factor interactions.
2. The Margolin nonorthogonal resolution IV two-level designs having m factors and $2m$ runs require fewer runs than their regular resolution IV 2^{m-k} counterparts.
3. A limited number of two-factor interactions can typically be estimated in some designs, though there is usually a great deal of partial aliasing among the two-factor interactions.

Disadvantages

1. Because of the nonorthogonality involved in many of the initial resolution III designs, main effects in the foldover design are not orthogonal. Hence there is some loss in estimation efficiency of main effects (though in many cases it is small).
2. The method of analysis is not as straightforward as orthogonal designs, but Miller and Sitter [8, 9] have suggested ways to analyze these foldover designs.

Supersaturated Designs

Supersaturated designs (see **Supersaturated Designs**) are most often used as screening experiments

to study factors occurring at two levels where the number of factors m being studied is at least as large as the number of runs N in the experiment. Because $N \leq m$ in a supersaturated design d , any such design must necessarily have main effects which are nonorthogonal to one another and have a complex aliasing structure. A number of methods for constructing supersaturated designs have been suggested, for example, see Lin [10, 11], Wu [12], and Nguyen [13, 14], and while these designs have been used successfully as screening experiments, they should be used with caution. The actual analysis of supersaturated designs and identification of significant main effects usually involves the use of some sort of regression variable selection technique.

Advantages

1. Run size economy. Supersaturated designs can be used to study a large number of factors using relatively few observations.

Disadvantages

1. The analysis of supersaturated designs is not as straightforward as that of orthogonal designs since parameter main effect estimates between factors are not necessarily orthogonal. The lack of orthogonality also leads to some inefficiency in terms of estimating main effects.
2. The aliasing structure of supersaturated designs is generally more complex than that of orthogonal and other nonorthogonal designs because $N < m$. Hence the same problems cited earlier for designs with complex aliasing structures hold here but to an even greater extent.

Mixed-Level Designs

While two-level designs are predominantly used as screening experiments, there are some screening situations where some factors must have more than two levels or where different factors might require different number of levels. For example, if a quantitative factor is believed to have a quadratic effect on the response, then it would be necessary to include at least three levels for the factor to detect the quadratic effect. In other situations, a qualitative factor might have more than two levels or an experiment might require the use of both qualitative and quantitative factors requiring different number of levels. To handle such experimental situations, there are a number

of designs available such as regular s^{m-k} FF designs, $s > 2$ or mixed-level designs, that is, designs containing factors with differing number of levels. However, because such designs are not used as often in screening experiments as two-level designs, we do not consider them for further discussion here.

Split-Plot Designs

Classical Agricultural Split-Plot Designs

The terminology used in the context of split-plot designs derives from its initial agricultural applications, where experiments were carried out on different plots of land. In these experiments, levels of one or more factors were assigned to large plots of land referred to as *whole plots*, while levels of other factors were assigned to smaller plots of land referred to as *split-plots* or *subplots*. This means that split-plot designs have two types of experimental units, whole plots and subplots. The smaller experimental units, the subplots, are nested within the larger ones, the whole plots. The importance of the split-plot structure for the design and analysis of experiments was first recognized by Fisher [1].

For example, in experiments for investigating the effect of different fertilizers and varieties on the yield of crops, the fertilizers are often sprayed from planes and large plots of land must then be treated with the same fertilizer. Crop varieties can be planted on smaller plots of land that are obtained by dividing up the large plots that were sprayed together. The larger plots of land are called *whole plots*, whereas the smaller plots are named *split-plots* or *subplots*. Because the levels of the factor fertilizer are applied to whole plots, it is called the *whole-plot factor* of the experiment. The second factor, crop variety, is applied to the subplots, and is referred to as the *subplot factor* of the experiment. A schematic representation of a split-plot design involving fertilizer as the whole-plot factor and variety as the subplot factor is given in Figure 1. In the figure, the levels of the whole-plot factor are represented by $F_1 - F_3$, and those of the subplot factor by $V_1 - V_3$. Evidently, split-plot designs with more than one whole-plot factor and more than one subplot factor can be constructed as well. In classical split-plot designs, all combinations of levels of the subplot factors occur within each combination of levels of the whole-plot factors.

The layout of the design in Figure 1 resembles that of a randomized block design (see **Blocking; Block Designs, Incomplete**). In a randomized block design however, the factor level combinations can be randomly assigned to the experimental units in the

Figure 1 Classical agricultural split-plot design where $F_1 - F_3$ and $V_1 - V_3$ represent the levels of the factors fertilizer and variety, respectively. The design has six whole plots (labeled Plot 1–6) each of which is divided into three subplots

blocks. In the split-plot design shown in Figure 1, such a complete random assignment of the factor level combinations to the subplots is impossible because all the subplots within one whole plot must be treated with the same fertilizer. Therefore, only a *restricted randomization* can be used. Typically, this restricted randomization is performed in two stages. First, the combinations of levels of the whole-plot factors are randomly assigned to the whole plots. Next, the combinations of levels of the subplot factor are randomly assigned to the subplots within each whole plot.

Classical Analysis of Data from Split-Plot Experiments

In the analysis of data from split-plot designs, the whole plots act as levels of a blocking factor (see **Blocking; Block Designs, Incomplete**). Therefore, *whole-plot effects* are included in the statistical model along with the whole-plot and subplot factors and advantages similar to the ones for block designs can

2 Split-Plot Designs

be obtained using split-plot designs. For example, the effect of the varieties in Figure 1 is calculated from the differences between the yields within each whole plot. As these differences eliminate the whole-plot effect, the effect of the varieties is measured with greater precision than the effect of the fertilizers. The calculation of the latter effect is not as precise because it involves calculating and comparing averages over all the subplots within a whole plot, and errors between subplots in different whole plots are usually larger than errors between subplots in a single whole plot. The effect of the whole-plot factor fertilizer is therefore tested against the *whole-plot error*, whereas the effect of the subplot factor variety is tested against the *subplot error*.

Traditionally, the whole-plot and subplot factors in a classical split-plot design are treated as categorical. The whole-plot effects are modeled using random effects (unlike block effects, which are typically modeled using fixed effects). The analysis of variance (ANOVA) model used to analyze the split-plot data can be written as

$$Y_{ijk} = \mu_{...} + \gamma_{i(j)} + \alpha_j + \beta_k + (\alpha\beta)_{jk} + \varepsilon_{ijk},$$

$$i = 1, \dots, m; j = 1, \dots, a; k = 1, \dots, b \quad (1)$$

with Y_{ijk} the response for the j th fertilizer and the k th variety in whole plot i , $\mu_{...}$ the overall mean, $\gamma_{i(j)}$ the random effect of the i th whole plot nested within the j th level of the whole-plot factor fertilizer, α_j the **main effect** of the j th fertilizer, β_k the main effect of the k th variety, $(\alpha\beta)_{jk}$ the interaction effect of the j th fertilizer and the k th variety, ε_{ijk} the random error, a the number of levels of the whole-plot factor, b the number of levels of the subplot factor, and m the number of whole plots at each whole-plot factor level. The constants α_j , β_k , and $(\alpha\beta)_{jk}$ are subject to the constraints $\sum_{j=1}^a \alpha_j = 0$, $\sum_{k=1}^b \beta_k = 0$, $\sum_{j=1}^a (\alpha\beta)_{jk} = 0$ for all k and $\sum_{k=1}^b (\alpha\beta)_{jk} = 0$ for all j to make the model estimable. The α_j , β_k , and $(\alpha\beta)_{jk}$ are the whole-plot effects, the subplot effects, and the whole-plot-by-subplot interaction effects, respectively. The random effects $\gamma_{i(j)}$ and ε_{ijk} are often referred to as *whole-plot error* and *subplot error*, respectively. The whole-plot errors $\gamma_{i(j)}$ are assumed to be independently normally distributed with zero mean and variance σ_γ^2 (the *whole-plot error variance*), and the subplot

errors ε_{ijk} are assumed to be independently normally distributed with zero mean and variance σ_ε^2 (the *subplot error variance*). It is also assumed that $\gamma_{i(j)}$ and ε_{ijk} are independent. These assumptions are identical to those made for randomized block designs with random block effects and imply that observations from different whole plots are independent, whereas observations within a whole plot are correlated. The resulting **correlation** structure of the responses is called *compound symmetric*. This structure is special in the sense that, while two observations in a given whole plot are correlated in advance of the experiment, they are independent once a whole plot has been selected.

A general ANOVA table for a classical two-factor split-plot design is given in Table 1. In the table, the whole-plot and subplot factors are denoted by A and B , respectively, and a , b , and m denote the number of levels of factor A , the number of levels of factor B , and the number of whole plots at each whole-plot factor level, respectively. The number of observations in the split-plot design equals $N = abm$. For the design in Figure 1, a , b , m , and N equal 3, 3, 2, and 18, respectively. The total number of whole plots in a classical split-plot design equals am and is denoted by c . For the example, that number is six.

An important aspect of split-plot designs is that the effects of the whole-plot factors are estimated less precisely than those of the subplot factors. This is taken into account in the ANOVA analysis. It implies that split-plot designs result in a low **power** for detecting whole-plot effects and a high power for detecting subplot effects. Because interactions between a whole-plot factor and a subplot factor are estimated precisely too, split-plot designs have a high power for detecting these as well. Ignoring the split-plot nature of the experiment and analyzing the data from a split-plot design as if they were data from a completely randomized experiment can lead to erroneous conclusions. Such an analysis typically underestimates the variance of the estimates of the whole-plot effects and overestimates the variance of the estimates of the subplot effects and the whole-plot-by-subplot interaction effects. Because of this, ignoring the split-plot nature of the design results in labeling the whole-plot effects as significant too often and in labeling the subplot effects and the whole-plot-by-subplot interaction effects as significant not often enough.

Industrial Split-Plot Experiments

Classical Industrial Split-Plot Experiments

Classical split-plot designs are not only applied in agriculture, but also in industrial and other settings. Although a better name for split-plot designs would therefore be *split-unit* designs, the original name of the design is still used in recent literature. An example of an industrial split-plot experiment is given in Box *et al.* [2]. The experiment was intended to investigate the corrosion resistance of steel bars treated with four different coatings C_1 , C_2 , C_3 , and C_4 at three duplicated furnace temperatures T_1 , T_2 , and T_3 (360, 370, and 380 °C, respectively). For each temperature, four differently coated bars were randomly arranged in the furnace. A schematic representation of this industrial split-plot design is shown in Figure 2, where the levels of the whole-plot factor, the furnace temperature, are represented by T_1 – T_3 , and those of the subplot factor, the coating, by C_1 – C_4 . In this experiment, the six runs of the furnace serve as the whole plots of the experiment and the four positions in the furnace can be interpreted as subplots. The furnace temperature and the coating are the whole-plot and subplot factors, respectively. When constructing the design, the temperatures are assigned to the runs of the furnace first. Next, the coatings are randomly assigned to the positions in the furnace. The split-plot design involving six operations of the furnace is more convenient and cheaper to conduct than a completely randomized design which would require 24 heatings each of which would be used for testing one single coating only.

The data for the corrosion resistance study depicted in Figure 2 are given in Table 2. The

Figure 2 Classical industrial split-plot design where T_1 – T_3 and C_1 – C_4 represent the levels of the factors temperature and coating, respectively. The design has six whole plots each of which contains four observations and corresponds to a run of the furnace

corresponding ANOVA table is displayed in Table 3. In the ANOVA table, the effect of the whole-plot factor temperature is tested against the whole-plot error. The effect of the subplot factor coating is tested against the subplot error, just like the interaction

Table 2 Data for the corrosion resistance study. The whole plots of the study are indicated in the column labeled WP. The columns labeled T , C , and y contain the furnace temperatures, coatings, and observed responses, respectively

WP	T	C	y	WP	T	C	y	WP	T	C	y

Total	49 638.62500	23			

effect between the two experimental factors. The main effects of the two factors are significant at the 1% level, whereas the interaction effect is significant at the 5% level. Note that the mean squared subplot error, which equals 124.54, is much smaller than the mean squared whole-plot error, which amounts to 4813.21. This shows that the errors between subplots in a single whole plot are much smaller than errors between subplots in different whole plots.

Other Industrial Split-Plot Experiments

As split-plot designs in industry often involve several quantitative whole-plot and subplot factors, and as, for reasons of cost and time, industrial experiments are frequently limited in size, classical split-plot designs are usually not satisfactory. As a matter of fact, classical split-plot designs in which all combinations of levels of one or more factors occur within levels of one or more other factors to allow for an ANOVA analysis (which involves the **estimation** of a large number of model parameters) are typically quite large. The split-plot designs used in industry and described in the literature on response-surface methodology (see **Response Surface Methodology**) therefore often look different from the classical ones. The main difference is that only a fraction of all combinations of subplot factor levels appear in every whole plot. In general, the analysis of data from these response-surface split-plot designs can be done using a regression approach rather than an ANOVA approach. For the analysis of two-level **factorial** split-plot designs and some specific two-level factorial split-plot designs however, a simpler ANOVA type of approach can still be used.

An example of a response-surface split-plot experiment in the food industry, where a regression approach is needed for analysis, was provided by

Trinca and Gilmour [3]. In this experiment, the impact of five factors on the yield of a protein extraction process was investigated: the feed position for the inflow of a mixture, the feed flow rate, the gas flow rate, and the concentrations of a protein A and a protein B. Twenty-one days were available for experimentation and three levels were used for each factor because the interest was in estimating a second-order response-surface model. The problem with this experiment was that setting the feed position could be done only once per day because it involved taking apart and reassembling the equipment. By keeping the position fixed during one day, two experimental runs could be performed per day instead of one, allowing 42 experimental runs in total. The split-plot design that was actually used is given in Table 4. In the table, the whole-plot factor, feed position of the inflow, is denoted by w and the subplot factors are denoted by s_1-s_4 . Notice that the level of the whole-plot factor does not change within each whole plot.

It is not always as obvious that experiments are run in a split-plot format as in the protein extraction experiment. In the following scenarios, a split-plot design is often used.

1. When different factor level combinations are tested while some other factor levels are not reset, then the resulting design is a split-plot design. This happens, for example, when experimenters try out different factor level combinations during one run of an oven. The oven temperature is not reset for all these observations. It is therefore the whole-plot factor of the experiment. The other factors are the subplot factors.
2. In two-stage experiments, it sometimes happens that some of the experimental factors are applied in the first stage, whereas others are applied in the

6 Split-Plot Designs

second stage. In those cases, batches of experimental material are often split in subbatches after the first stage. The subbatches then undergo different treatments dictated by the levels of the factors applied in the second stage of the experiment. The factors applied in the first stage are the whole-plot factors, whereas those applied in the second stage are the subplot factors. In experiments involving more than two stages, more complicated designs than split-plot designs are used. Examples of such designs for multistage experiments in the semiconductor industry can be found in Mee and Bates [4].

- Experiments for simultaneously investigating the impact of ingredients of a mixture and of process factors, i.e. mixture-process variable experiments, are frequently conducted as split-plot experiments [5]. This can happen in two ways. First, several batches can be prepared that undergo different process conditions. In that case, the ingredients of the mixture are the whole-plot factors and the factors determining the tested process conditions act as subplot factors. Second, processing conditions can be held fixed while consecutively trying out different mixtures. In that case, the ingredients of the mixture are the subplot factors of the design.
- When experimental designs need to be run sequentially, experimenters are often reluctant to change the levels of one or more factors because this is impractical, time consuming, or expensive. All the observations that are obtained by not resetting the levels of the *hard-to-change factors*

then play the role of a whole plot. The hard-to-change factors are the whole-plot factors of the design, whereas the remaining factors are subplot factors. A useful reference in this context is Webb *et al.* [6].

- A special case of an experiment involving hard-to-change factors is a *prototype experiment*, in which the levels of some of the factors define a prototype, whereas the levels of other factors determine operating conditions under which the prototype is tested. As changing the levels of a prototype factor involves assembling a new prototype, these levels are held constant for several observations under different operating conditions. In that type of experiment, the factors related to the prototype are the whole-plot factors, whereas the ones connected to the operating conditions serve as subplot factors. Prototype experiments run using split-plot designs are discussed in Bisgaard and Steinberg [7].
- As indicated in Box and Jones [8], robust product experiments (*see Robust Design*) involving crossed arrays are often run as split-plot designs. Often, this is because the noise factors are hard to control and changing their levels is cumbersome. An interesting feature of split-plot designs for robust product experimentation is that control-by-noise interaction effects can be estimated more precisely than by using a completely randomized experiment.

A common denominator of these industrial split-plot experiments is that the levels of some of

the factors are not independently reset for several observations. The groups of observations for which these levels were not reset constitute the whole plots of the experimental design. The number of observations in each of these groups is the number of subplots. In many of the scenarios described above, though not always, the number of subplots within each whole plot is dictated by practical considerations such as the number of observations that can be made in one day, using one batch or in one oven run. In those cases, the numbers of subplots within each whole plot are equal. However, the regression or response-surface analysis of data from split-plot designs can handle situations in which the numbers of subplots are unequal across whole plots. Goos [9] demonstrates it can be advantageous in terms of design efficiency to use unequal numbers of subplots within each whole plot.

Response-Surface Split-Plot Model and Analysis

Response-Surface Model

The data from industrial response-surface split-plot designs with c whole plots and $n_1, \dots, n_c$ subplots in each of them can in general be analyzed by means of a regression approach. If the levels of the k whole-plot factors and the l subplot factors in the design are denoted by $\mathbf{w} = [w_1, \dots, w_k]'$ and $\mathbf{s} = [s_1, \dots, s_l]'$ respectively, then the regression model can be written as

$$Y_{ij} = \mathbf{f}'(w_i, s_{ij})\boldsymbol{\beta} + \gamma_i + \varepsilon_{ij} \quad (2)$$

where Y_{ij} represents the response of the j th observation in the i th whole plot, $\mathbf{w}_i$ contains the levels of the k whole-plot factors in that whole plot, $\mathbf{s}_{ij}$ contains the levels of the l subplot factors at

the j th observation in the i th whole plot, $\boldsymbol{\beta}$ is the p -dimensional vector of unknown factor effects, and γ_i and ε_{ij} are the i th whole-plot error and the subplot error associated with the j th observation in the i th whole plot, respectively. Finally, $\mathbf{f}(\mathbf{w}_i, \mathbf{s}_{ij})$ contains the p -dimensional model expansion of the experimental factors. The model expansion typically contains the levels of the factors (corresponding to the factors' linear effects), their cross-products (corresponding to interactions) and, for second-order models, their squares (corresponding to the quadratic effects). In matrix notation, and denoting $n = \sum_{i=1}^c n_i$, the model can be written as

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\varepsilon} \quad (3)$$

where $\mathbf{Y} = [Y_{11}, \dots, Y_{cn_c}]'$, $\mathbf{X} = [\mathbf{f}(\mathbf{w}_1, \mathbf{s}_{11}), \dots, \mathbf{f}(\mathbf{w}_c, \mathbf{s}_{cn_c})]'$ represents the $n \times p$ model matrix, $\mathbf{Z}$ is an $n \times c$ matrix of zeros and ones assigning the n runs to the c whole plots, $\boldsymbol{\gamma}$ is the c -dimensional vector containing the random effects of the c whole plots, and $\boldsymbol{\varepsilon}$ is the n -dimensional vector containing the random errors. It is assumed that

$$E(\boldsymbol{\varepsilon}) = \mathbf{0}_n \text{ and } \text{cov}(\boldsymbol{\varepsilon}) = \sigma_\varepsilon^2 \mathbf{I}_n \quad (4)$$

$$E(\boldsymbol{\gamma}) = \mathbf{0}_c \text{ and } \text{cov}(\boldsymbol{\gamma}) = \sigma_\gamma^2 \mathbf{I}_c \quad (5)$$

and

$$\text{cov}(\boldsymbol{\gamma}, \boldsymbol{\varepsilon}) = \mathbf{0}_{c \times n} \quad (6)$$

Under these assumptions, the **covariance** matrix of the responses, $\text{var}(\mathbf{Y})$, is

$$\mathbf{V} = \sigma_\varepsilon^2 \mathbf{I}_n + \sigma_\gamma^2 \mathbf{Z}\mathbf{Z}' \quad (7)$$

which is a block diagonal matrix if the entries of $\mathbf{Y}$ are grouped per whole plot. For example, for a design with two whole plots of three observations and one whole plot of two observations, the covariance matrix equals

$$\mathbf{V} = \begin{bmatrix} \sigma_\varepsilon^2 + \sigma_\gamma^2 & \sigma_\gamma^2 & \sigma_\gamma^2 & 0 & 0 & 0 & 0 & 0 \\ \sigma_\gamma^2 & \sigma_\varepsilon^2 + \sigma_\gamma^2 & \sigma_\gamma^2 & 0 & 0 & 0 & 0 & 0 \\ \sigma_\gamma^2 & \sigma_\gamma^2 & \sigma_\varepsilon^2 + \sigma_\gamma^2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \sigma_\varepsilon^2 + \sigma_\gamma^2 & \sigma_\gamma^2 & \sigma_\gamma^2 & 0 & 0 \\ 0 & 0 & 0 & \sigma_\gamma^2 & \sigma_\varepsilon^2 + \sigma_\gamma^2 & \sigma_\gamma^2 & 0 & 0 \\ 0 & 0 & 0 & \sigma_\gamma^2 & \sigma_\gamma^2 & \sigma_\varepsilon^2 + \sigma_\gamma^2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & \sigma_\varepsilon^2 + \sigma_\gamma^2 & \sigma_\gamma^2 \\ 0 & 0 & 0 & 0 & 0 & 0 & \sigma_\gamma^2 & \sigma_\varepsilon^2 + \sigma_\gamma^2 \end{bmatrix} \quad (8)$$

Model Estimation and Inference

Because of the correlation between the observations from a split-plot design, the best linear unbiased estimator of the model parameters contained within β is the generalized least-squares estimator

$$\hat{\beta} = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{y} \quad (9)$$

with covariance matrix

$$\text{var}(\hat{\beta}) = (\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1} \quad (10)$$

To use these expressions, the whole-plot and subplot error variances σ_γ^2 and σ_ε^2 contained within $\mathbf{V}$ have to be replaced by estimates. In the response-surface split-plot design literature, two approaches are advocated to estimate the variances. The first approach, restricted (or residual) maximum-likelihood estimation, is generally applicable to any split-plot design and was recommended by Letsinger *et al.* [10]. The second approach uses pure error estimates for the whole-plot and subplot error variances and can be applied only if the design has replicated points. This approach offers the advantage that the estimates of the **variance components** σ_ε^2 and σ_γ^2 do not depend on the specification of the model, $\mathbf{f}'(\mathbf{w}_i, \mathbf{s}_{ij})\beta$. It is outlined in Vining *et al.* [11]. A disadvantage is that replications and thus a large experiment are required for estimating the variance components, which are not of primary interest to the experimenter.

The statistical inference for split-plot response-surface designs is not straightforward. First, it is not clear what denominator **degrees of freedom** have to be used for the hypothesis tests. Goos *et al.* [12] show that the approach suggested in Kenward and Roger [13] is best in terms of controlling the type I error if generalized least-squares estimation is combined with restricted maximum likelihood. Second, industrial split-plot designs sometimes have a small number of whole plots so that the whole-plot error variance is not estimable or cannot be estimated accurately. In such situations, the Bayesian approach of Gilmour and Goos [14] to analyze data from split-plot designs is recommended. Also, it is not clear what degrees of freedom to use when the pure error estimation approach of Vining *et al.* [11] for the variance components is used. The good performance of restricted maximum likelihood with the Kenward and Roger option for determining the denominator degrees of freedom for hypothesis tests, together

with the growing availability of software, makes this combination the current state-of-the-art method for analyzing data from split-plot designs.

Simplified Analysis for Two-Level Designs

For two-level factorial split-plot designs and for the two-level **fractional factorial** designs described in Huang *et al.* [15], Bingham and Sitter [16], and Bingham *et al.* [17, 18], a simplified analysis is possible because the generalized least-squares estimator produces the exact same estimates as the ordinary least-squares estimator. As a result, estimating the model from such a design can be done in the same fashion as for completely randomized two-level factorial and fractional factorial designs (*see* **Factorial Experiments; Fractional Factorial Designs**). An appropriate ANOVA then consists of two separate parts just like the classical analysis in Table 1. Bisgaard [19] however prefers using half-normal plots to identify significant effects just like for completely randomized two-level designs (*see* **Half-Normal Plot**). It is important however that separate half-normal plots are prepared for the whole-plot effects and for the subplot effects because they are estimated with a different precision. Alternatively, Lenth's method (*see* **Lenth's Method for the Analysis of Unreplicated Experiments**) can be applied separately to each set of effects.

Design of Response-Surface Split-Plot Experiments

Several construction methods for split-plot designs can be found in the literature. A distinction between methods for first- and second-order response-surface designs can be made.

First-Order Split-Plot Response-Surface Designs

The design of two-level factorial and fractional factorial split-plot experiments has been discussed by Huang *et al.* [15], Bingham and Sitter [16], and Bingham *et al.* [17, 18] (*see also* **Fractional Factorial Designs**). The design of fractional factorial split-plot experiments for robust parameter design (*see* **Product Array Designs**) received attention in Bingham and Sitter [20]. The design criterion used by these authors is an extension of the

minimum aberration criterion (see **Minimum Aberration**).

Standard Second-Order Split-Plot Designs

Vining *et al.* [11] suggest using modified central composite designs and Box–Behnken designs for conducting second-order split-plot experiments. The **central composite** and Box–Behnken designs are modified and arranged in whole plots so that the generalized least-squares estimator (which takes into account the split-plot error structure of the data) produces the same estimates as the ordinary least-squares estimator (which ignores the split-plot nature of the experiment). These so-called *equivalent-estimation designs* have a lot of observations at the **center point** to allow for a pure error estimate of the variance components. A drawback of the designs is that, despite their sizes, they lead to imprecise estimates of the model parameters. This is because a large part of the designs consists of replicated center points for the pure error estimation of the variance components. These replicates provide no information about the factor effects. Also, it is not clear how the standard designs can be adapted for different numbers and sizes of whole plots.

Tailor-Made Split-Plot Response-Surface Designs

Two approaches have been presented in the literature to construct tailor-made second-order response-surface designs. Trinca and Gilmour [3] suggest a sequential approach for constructing *multistratum designs*, a special case of which are split-plot designs. For split-plot designs, the sequential approach starts by selecting a design for the whole-plot factors. Next, a design for the subplot factors is chosen, and an algorithmic approach is used to assign the factor level combinations in that design to the whole plots. The algorithm searches for a split-plot design that is as orthogonal as possible. A second approach that can be used for constructing tailor-made split-plot designs is the optimal design approach (see also **Optimal Design**). This approach is advocated by Goos [21] and in general leads to precise parameter estimates and accurate predictions. In theory (and unlike the sequential approach of Trinca and Gilmour [3]), the optimal designs depend on the (unknown) ratio of the whole-plot error variance σ_γ^2

to the subplot error variance σ_ε^2 , which has to be specified by the experimenter. Fortunately however, specifying different ratios of the variance components within the range of practical values usually leads to the same design when the optimal design approach is used. The practical range of the ratio of the whole-plot error variance to the subplot error variance is 0.5–10. Algorithms for computing D-optimal split-plot designs have been proposed by Goos and Vandebroek [22] and Jones and Goos [23]. Goos and Donev [24] show how to adapt the optimal design approach to include replicated points in the designs and to allow lack-of-fit tests to be conducted.

The two approaches for constructing tailor-made split-plot designs are flexible in that they can be used for any number and size of whole plots. They can also handle constraints on the factor levels and situations involving different types of factors, i.e., they can be used for problems involving quantitative, categorical, and/or mixture factors.

Extensions and Related Designs

Experiments involving more than two stages will sometimes have factors that are applied at each of these stages. In such cases, the resulting design will often be a *split-split-plot design*. A similar design might be useful when there are several hard-to-change factors. In such cases, the factor that is hardest to change will be reset the smallest number of times, and factors that are easier to change will be reset more often (but not as often as easy-to-change factors). More complicated designs than split-plot and split-split-plot designs for multistage experiments are discussed in Mee and Bates [4].

Split-plot and split-split-plot type of designs are often used inadvertently when experimental designs are run sequentially. This is because it is not sufficient to run a design in a random order to have a completely randomized design with observations that are statistically independent. For this to be the case, it is important that the levels of all the factors are reset for every single observation even when the level of one or more factors is the same in two successive runs. If this is not done, then it is unrealistic to assume that the successive runs are independent from each other and an analysis that takes into account

the correlation pattern is recommended. Details about this type of experimental approach can be found in Webb *et al.* [6]. In case resetting the factors levels for every run is impossible for reasons of time or cost, it is however better to construct a proper split-plot design using one of the methods outlined above rather than to use a random run order and not reset the factors levels. This is because, for properly designed split-plot experiments, many of the parameter estimates are often independent from each other, while this is not true for *randomized-not-reset experiments* in general. Also, the parameter estimates from a designed split-plot experiment will usually be more precise.

Supersaturated Designs

Introduction

A supersaturated design is essentially a **fractional factorial** design in which the number of experimental runs (observations) is less than the number of parameters to be estimated. These designs are useful as screening tools, as the paring of candidate factors is performed in a cost-efficient manner.

Consider the simple fact that where there is an effect, there is a cause. Quality engineers are constantly faced with distinguishing between the factors which have a real effect and those estimated effects that are due to random error. Those “null” factors are then adjusted to lower the cost; those “nonnull” (effective) factors are used to yield better quality. Often, a large number of factors can be listed as possible sources of effect and among those factors only a small portion are actually active. This is sometimes called *effect sparsity*. A problem frequently encountered in this area is how to reduce the total number of experiments.

In order to obtain an unbiased estimate of the **main effect** of each factor, the number of experiments must exceed (or at least be equal to) the number of factors plus one (for estimating the overall grand average). When these two are equal, the design is called a *saturated design* and is the minimum effort required to estimate all main effects. The standard advice given to users in such a screening process is to use the saturated design, which is “optimal” according to certain theoretical optimality criteria. However, the nonsignificant effects are not of interest. Estimating all main effects may be wasteful if the goal is simply to detect those few active factors. If the number of active factors is indeed small, the use of a slightly biased estimate will still allow one to accomplish the identification of the active factors but significantly reduce the amount of experimental work. This is particularly important in situations where the cost of an individual run is high. Developing such **screening designs** has long been a well-recognized problem, certainly since Satterthwaite [1].

When all factors can be reasonably arranged into several groups, the so-called group screening designs can be used (see [2, 3]). Only those factors in groups that are found to have large effects are studied further. The grouping scheme seems to be crucial but has

seldom been discussed. While such methods may be appropriate in certain situations (e.g., blood tests), we are interested in systematic supersaturated designs that can examine k factors in $N < k + 1$ experiments in which no grouping scheme needs to be made.

Optimality Criteria

Optimality criteria that are useful for characterizing the quality of supersaturated designs are discussed in this section. When a supersaturated design is employed, the abandonment of orthogonality is inevitable. It is well known that lack of orthogonality results in lower efficiency; therefore we seek a design that is as “near orthogonal” as possible. One way to measure the degree of nonorthogonality between two columns, c_i and c_j , is to consider their cross-product $s_{ij} = c'_i c_j$. A design is orthogonal when all $s_{ij} = 0$. A larger $|s_{ij}|$ implies less orthogonality. Intuitively, a design should be efficient if $E(s^2)$, the average value of s_{ij}^2 over all pairs is small. This criterion, first proposed by Booth and Cox [4], is given by:

$$E(s^2) = \sum_{1 \leq i < j \leq k} \frac{s_{ij}^2}{\binom{k}{2}} \quad (1)$$

Alternatively, one could consider the maximal value of either $|s_{ij}|$ or s_{ij}^2 over all pairs as a criterion.

For three-level supersaturated designs, Yamada and Lin [5] defined a measure of dependency between two design columns $\chi^2(\mathbf{x}_i, \mathbf{x}_j) = \sum_{u,v=1}^3 \frac{(n_{uv}^{(ij)} - n/9)^2}{n/9}$, where $n_{uv}^{(ij)}$ is the number of (u, v) pairs in $(\mathbf{x}_i, \mathbf{x}_j)$. Then they defined a criterion for the whole design $\mathbf{X}$ by

$$\text{ave} \chi^2 = \sum_{1 \leq i < j \leq k} \frac{\chi^2(\mathbf{x}_i, \mathbf{x}_j)}{\binom{k}{2}} \quad (2)$$

and also showed a lower bound of $\text{ave} \chi^2 \geq \frac{2n(2k - n + 1)}{(n - 1)(k - 1)}$.

Recently, Fang *et al.* [6] proposed a general criterion for supersaturated design, suitable for any mixed-level design. For any two design columns $\mathbf{x}_i$ and $\mathbf{x}_j$, define $f_{\text{NOD}}^{ij} = \sum_{u=1}^{q_i} \sum_{v=1}^{q_j} \left(n_{uv}^{(ij)} - \frac{n}{q_i q_j} \right)^2$, where

2 Supersaturated Designs

$n_{uv}^{(ij)}$ is the number of (u, v) pairs in $(\mathbf{x}_i, \mathbf{x}_j)$, and $n/(q_i q_j)$ stands for the average frequency of level combinations in each pair of columns $\mathbf{x}_i$ and $\mathbf{x}_j$. A new criterion $E(f_{\text{NOD}})$ is defined as the following,

$$E(f_{\text{NOD}}) = \sum_{1 \leq i < j \leq k} \frac{f_{\text{NOD}}^{ij}}{\binom{k}{2}} \quad (3)$$

It is obvious that $E(f_{\text{NOD}}) = 0$ for an **orthogonal array**. Let $\lambda_{ml} = \sum_{j=1}^k 1_{\{x_{mj}=x_{lj}\}}$, where 1_A is the indicator function of A , that is, λ_{ml} is the number of coincidences between the two columns $\mathbf{x}_m$ and $\mathbf{x}_l$. It is obvious that $\lambda_{mm} = k$. It can be shown [6] that

$$\begin{aligned} E(f_{\text{NOD}}) &= \frac{\sum_{m,l=1, m \neq l}^n \lambda_{ml}^2}{k(k-1)} + C(n, q_1, \dots, q_k) \\ &\geq \frac{n \left(\sum_{j=1}^k n/q_j - k \right)^2}{k(k-1)(n-1)} \\ &\quad + C(n, q_1, \dots, q_k) \end{aligned} \quad (4)$$

where $C(n, q_1, \dots, q_k) = \frac{nk}{k-1} - \frac{1}{k(k-1)} \left(\sum_{i=1}^k \frac{n^2}{q_i} + \sum_{i,j=1, j \neq i}^k \frac{n^2}{q_i q_j} \right)$ depends on $\mathbf{X}$ only through $n, q_1, \dots, q_k$, and the lower bound of $E(f_{\text{NOD}})$ can be achieved if and only if $\lambda = \left(\sum_{j=1}^k n/q_j - k \right) / (n-1)$ is a positive integer and all λ_{ml} 's ($m \neq l$) are equal to λ .

For any two factors $\mathbf{x}_i$ and $\mathbf{x}_j$ of the design $\mathbf{X}$, the equal occurrence of -1 and 1 implies that $f_{\text{NOD}}^{ij} = \sum_{u,v=-1,1} \left(n_{uv}^{(ij)} - n/4 \right)^2 = s_{ij}^2/4$. This, in turn, implies that f_{NOD}^{ij} is essentially the same measure as s_{ij}^2 for two-level designs, and as $\chi^2(\mathbf{x}_i, \mathbf{x}_j) = f_{\text{NOD}}^{ij} q_i q_j / n$ for three-level columns. Namely, $E(f_{\text{NOD}}) = \frac{1}{4} E(s^2)$ and $\frac{n}{9} \text{ave} \chi^2$ when all $q_i = 2$ and 3 , respectively.

All the above criteria, however, are only for pairwise relationships. More general criteria have been obtained in Wu [7] and Deng *et al.* [8, 9]. One important feature of the goodness of a supersaturated screening design is its projection property (see [10, 11, 12]). Deng *et al.* [13, 14] thus proposes the r-rank

criterion as *the resolution rank (or r-rank, for short) of $\mathbf{X}$ is defined as $f = d - 1$, where d is the minimum number of subset columns that are linearly dependent.* Detailed properties of r-rank can be found in Deng *et al.* [14].

Supersaturated Designs Using Hadamard Matrices

In this section we discuss some basic methods for constructing supersaturated designs. Lin [15] proposed a class of special supersaturated designs which can be easily constructed via half fractions of the Hadamard matrices. These designs can examine $k = N - 2$ factors with $n = N/2$ runs, where N is the order of the Hadamard matrix used. The Plackett and Burman [16] designs, which can be viewed as a special class of Hadamard matrices, are used to illustrate the basic construction method.

Table 1 shows the original 12-run Plackett and Burman design. We will take column 11 as a *branching* column, meaning that we divide the 12 runs into two groups of 6 runs each, in accord with the sign in column 11. Then the runs (rows) can be split into two groups: group I with the sign of $+1$ in column 11 (rows 2, 3, 5, 6, 7, and 11), and group II with the sign of -1 in column 11 (rows 1, 4, 8, 9, 10, and 12). Deleting column 11 from group I causes columns 1–10 to form a supersaturated design to examine $N - 2 = 10$ factors in $N/2 = 6$ runs (runs 1–6, as indicated in Table 2). It can be shown that if group II is used, the resulting supersaturated design is an equivalent one. In general, a Plackett and Burman [16] design matrix can be split into two half fractions according to a specific branching column whose signs equal $+1$ or -1 . Specifically, take only the rows that have $+1$ in the branching column. Then, the $N - 2$ columns other than the branching column will form a supersaturated design for $N - 2$ factors in $N/2$ runs. Judged by $E(s^2)$, these designs have been shown to be optimal among all other existing supersaturated designs [17].

Moreover, the half-fraction Hadamard matrix of order $n = N/2 = 4t$ is closely related to a *balanced incomplete block design* with $(v, b, r, k) = (2t - 1, 4t - 2, 2t - 2, t - 1)$ and $\lambda = t - 1$. Consequently, the $E(s^2)$ value for a supersaturated design from a half-fraction Hadamard matrix is $n^2(n - 3)/[(2n - 3)(n - 1)]$, which can be shown to

Table 1 A supersaturated design derived from the Hadamard matrix of order 12

be the minimum within the class of designs with same size. Potentially promising theoretical results seem possible for the construction of a half-fraction Hadamard matrix. Theoretical implications deserve detailed scrutiny and are discussed below. For more details regarding this issue, see Cheng [17] and Nguyen [18]. The half-fraction idea can be generalized to fractions of higher-level orthogonal arrays for construction of higher-level supersaturated designs [6].

Note that the interaction columns of Hadamard matrices are only partially confounded with other main-effect columns [10, 11]. Wu [7] makes use of such a property and proposes a supersaturated design that consists of all main-effect and two-factor interaction columns from any given Hadamard matrix of order N . The resulting design has N runs and can accommodate up to $N(N-1)/2$ factors, namely, $N-1$ columns from main effects and $(N-1)(N-2)/2$ columns from interaction effects. When there are $k < N(N-1)/2$ factors to be studied, choosing columns becomes an important issue to be addressed. Provided the interactions are not fully confounded with the main effects, Lin [19] extended

this idea to analyze interaction effects for first-order designs.

Data Analysis Methods

Several methods have been proposed in the literature to analyze the experimental data, given that the number of potential effects exceeds the number of observations. The stepwise regression procedure is probably the most popular one. Chen and Lin [20] show that the largest effect can always be identified, under some very mild conditions. Recent advances in this area, including adjusted p value, Bayesian, and penalized least-squares methods, are discussed below.

Adjusted p -Value Method

When studying so many effects in only a few runs, the probability of a false-positive reading (type I error) is a major risk. Recall that we have null and alternative pairs $H_j : \beta_j = 0$ and $H_j^c : \beta_j \neq 0$. Forward selection proceeds by identifying the maximum F statistics at successive stages. Let $\mathbf{S}$ denote the

4 Supersaturated Designs

complete set of potential effects and $j_1, \dots, j_{s-1}$ denote the effects selected at the first $s - 1$ stages. The F statistic for testing H_j at stage s is then $F_j^{(s)} = \text{SSR}(j|j_1, \dots, j_{s-1})/\text{MSE}(j, j_1, \dots, j_{s-1})$ (SSR: Sum Square Regression; MSE: Mean Square Error). Choose the new effect by

$$j_s = \arg \max_{j \in S - \{j_1, \dots, j_{s-1}\}} F_j^{(s)} \quad (5)$$

Letting $\max F_j^{(s)} = F^{(s)}$ and $p^{(j)} = \text{Prob}\{F^{(j)} > f^{(j)} | \text{all previous } H_i \text{ are true}\}$, where $f^{(j)}$ is the observed value of $F^{(s)}$. The forward selection procedure is defined by selecting variables $j_1, \dots, j_f$, where $p^{(f)} \leq \alpha$ and $p^{(f+1)} > \alpha$. If $p^{(1)} > \alpha$, then no variables are selected.

Algorithmically, at stage j , if $p^{(j)} > \alpha$, then stop; otherwise, enter X_j and continue. This procedure controls the type I error rate exactly at level α under the complete null hypothesis since P (rejects at least one H_i | all H_i true) $= P(F^{(1)} \leq f_\alpha^{(1)}) = \alpha$. In addition, if the first s variables are *forced* and the test is used to evaluate the significance of the next entering variable (of the remaining $k - s$), the procedure is again exact under the complete null hypothesis of no effects among the $k - s$ remaining variables. The exactness disappears with simulated p values, but the errors can be made very small, particularly with control variates. The analysis of data from supersaturated designs along this direction can be found in Westfall *et al.* [21].

Bayesian Method

Beattie *et al.* [22] detail a two-stage Bayesian model selection strategy combining recent methodologies: the stochastic search variable selection (SSVS) method and the intrinsic Bayes factor (IBF) method. The two-stage procedure is able to keep all possible models under consideration while providing a level of robustness akin to Bayesian analyses incorporating noninformative priors. Note that Bayesian methods are able to supplement observational information using prior information on the parameters. This allows straightforward computation of posterior probabilities, a more intuitive concept than the p value. Recent development of the Gibbs sampling algorithm and other Markov chain Monte Carlo techniques, in tandem with computational advances, have brought many Bayesian ideas into the mainstream.

However, the use of these methods in analyzing supersaturated designs may require a departure from noninformative priors to guarantee the existence of a proper posterior distribution, thus leaving room for controversy on the objectivity of the results.

Penalized Least-Squares Method

Li and Lin [23] proposed a variable selection procedure for identifying active factors in supersaturated designs, via nonconvex penalized **least squares**. Suppose that observations $y_1, \dots, y_n$ are an independent sample from the linear regression model

$$y_i = x_i^T \beta + \epsilon_i \quad (6)$$

with $E(\epsilon_i) = 0$, and $\text{Var}(\epsilon_i) = \sigma^2$, where x_i corresponds to a fixed experiment design. Define a penalized least-squares function as

$$Q(\beta) \equiv \frac{1}{2n} \sum_{i=1}^n (Y_i - x_i^T \beta)^2 + \sum_{j=1}^d p_\lambda(|\beta_j|) \quad (7)$$

where $p_\lambda(\cdot)$ is a penalty function, and λ may depend on the **sample size** n and is a tuning parameter, which controls model complexity and can be selected by some data-driven methods. Fan and Li [24] and Li and Lin [23, 25] applied the generalized cross validation to choose λ .

Fan and Li [24] studied the issue of selection of penalty function in depth and advocated the use of the smoothly clipped absolute deviation (SCAD), whose first-order derivative is defined by

$$p'_\lambda(\beta) = \lambda \left\{ I(\beta \leq \lambda) + \frac{(a\lambda - \beta)_+}{(a-1)\lambda} I(\beta > \lambda) \right\} \quad (8)$$

for some $a > 2$ and $\beta > 0$

with $p_\lambda(0) = 0$. In our analysis, we use $a = 3.7$ as advocated in Fan and Li [24]. Given an initial value $\beta^{(0)}$ that is close to the true value of β , when $\beta_j^{(0)}$ is not very close to 0, the penalty $p_\lambda(|\beta_j|)$ can be locally approximated by a quadratic function as $[p_\lambda(|\beta_j|)]' = p'_\lambda(|\beta_j|) \text{sgn}(\beta_j) \approx \{p'_\lambda(|\beta_j^{(0)}|)/|\beta_j^{(0)}|\} \beta_j$, otherwise, set $\hat{\beta}_j = 0$. With the local quadratic approximation, the solution for the penalized least squares can be found by iteratively computing the following **ridge** regression with an initial value $\beta^{(0)}$: $\beta^{(1)} = \{X^T X + n \Sigma_\lambda(\beta^{(0)})\}^{-1} X^T y$, where $\Sigma_\lambda(\beta^{(0)}) = \text{diag}\{p'_\lambda(|\beta_1^{(0)}|)/|\beta_1^{(0)}|, \dots, p'_\lambda(|\beta_d^{(0)}|)/|\beta_d^{(0)}|\}$. For

analysis of supersaturated design, Li and Lin [23, 25] set the level of significance to be 0.1 for both F enter and F remove in the stepwise variable selection procedure for choosing an initial value for the penalized least-squares approaches.

Example: Williams Rubber Experiment

The original problem given in Williams [26] concerned the effects of 24 experimental factors, and 28 runs of a Plackett and Burman design were used. The full data display was also given in Box and Draper [27, p. 175]. Note that columns 13 and 16 are fully confounded in the original setup. Taking the unused orthogonal column (+ - + + - + - + + + - - + - - - + - - - + + + + - - +) as the branching column results in a supersaturated design with 14 runs, as displayed in Table 3 (with corresponding observations). Using the entire data set of 28 observations, Williams [26] identified factors 4,

10, 15, and 20 as the most influential. This result will be viewed as the **benchmark** for all comparisons.

Lin [15] utilized a forward selection procedure on this half fraction for identifying the most important factors. His analysis also identified these four factors in addition to factor 12. Note that sequential selection procedures are prone to overfitting. It is worth mentioning that a stepwise procedure utilizing the AIC criterion (implemented in S-Plus) selected factor 15 only.

The **adjusted p -value** method [21] used **resampling** to estimate the distribution of the maximal F statistic at each step of the procedure. They used those estimates to adjust the p -value cutoffs for inclusion in forward selection. Using their methodology on the Williams half-fraction data set, they concluded that only factor 15 was active.

For the Bayesian method [22], {4, 12, 15, 20} was chosen by the selections of the SSVS algorithm as the model for input into the IBF scheme. The IBF follow-up procedure to SSVS results in a

more moderate, stable final model, with four factors selected from the factors identified by SSVS. Note that the result from the two-stage procedure is *insensitive* to the estimate of σ^2 . Using the all-subsets regression procedure recommended by Abraham *et al.* [28], assuming five or fewer active factors, yields the same four-factor model as the two-stage procedure. However, the Bayesian approach does not need to specify the number of active factors in advance.

The penalized least-squares method [23] identified {4, 12, 15, 20} as the final model. Table 4 summarizes the results of the various analytical techniques applied to the Williams half-fraction experiment. The classical stepwise techniques tend to be either very conservative (using $p = 0.01$), selecting one factor, or very liberal (with $p = 0.10$), selecting 12 factors (not shown in the table). The SSVS/IBF agrees closely with the conservative stepwise methods but while using a different estimate is extremely liberal in factor inclusion.

Theoretical Construction Methods

Deng *et al.* [14] proposed a supersaturated design of the form $\mathbf{X}_c = [\mathbf{H}, \mathbf{RHC}]$, where $\mathbf{H}$ is a normalized Hadamard matrix, $\mathbf{R}$ is an orthogonal matrix, and $\mathbf{C}$ is an $n \times (n - c)$ matrix representing the operation of column selection. The $\mathbf{X}_c$ matrix covers many existing supersaturated designs. This includes the supersaturated designs proposed by Lin [15], Wu [7], Yamada and Lin [29], and Tang and Wu [30]. It can be shown that

$$\mathbf{X}_c' \mathbf{X}_c = \begin{pmatrix} n\mathbf{I}_n & \mathbf{H}'\mathbf{RHC} \\ \mathbf{C}'\mathbf{H}'\mathbf{R}'\mathbf{H} & n\mathbf{I}_{n-c} \end{pmatrix} = \begin{pmatrix} n\mathbf{I}_n & \mathbf{WC} \\ \mathbf{C}'\mathbf{W}' & n\mathbf{I}_{n-c} \end{pmatrix} \quad (9)$$

where $\mathbf{W} = \mathbf{H}'\mathbf{RH} = (w_{ij}) = (\mathbf{h}_i'\mathbf{R}\mathbf{h}_j)$ and $\mathbf{h}_j$ is the j th column of $\mathbf{H}$. Following the argument in Tang and Wu [30] and the theorem below, these designs will always have the minimum $E(s^2)$ values within the supersaturated design of this type.

Theorem 1 Let $\mathbf{H}$ be a Hadamard matrix of order n and $\mathbf{B} = (b_1, \dots, b_r)$ be a $n \times r$ matrix with all entries ± 1 and $\mathbf{V} = \mathbf{H}'\mathbf{B} = (v_{ij}) = \mathbf{h}_i'b_j$, then for any fixed $1 \leq j \leq r$, $n^2 = \sum_{i=1}^n v_{ij}^2$. Furthermore, let $\mathbf{B} = \mathbf{RH}$ and $\mathbf{W} = \mathbf{H}'\mathbf{RH} = (w_{ij})$. We have

1. $\frac{1}{n}\mathbf{W}$ is an $n \times n$ orthogonal matrix,
2. $n^2 = \sum_{i=1}^n w_{ij}^2 = \sum_{j=1}^n w_{ij}^2$,
3. w_{ij} is always a multiple of 4, and
4. if $\mathbf{H}'$ is column balanced, then $\pm n = \sum_{i=1}^n w_{ij} = \sum_{j=1}^n w_{ij}$.

Extension of these results to a more general class of supersaturated designs in the form $\mathbf{S}_K = (\mathbf{R}_1\mathbf{H}\mathbf{C}_1, \dots, \mathbf{R}_K\mathbf{H}\mathbf{C}_K)$ are promising (see [31, 29]). Combinatorial construction methods for supersaturated designs have also been studied, some results can be found in Fang *et al.* [32]. Other recent advances for construction methods are discussed below.

Marginally Oversaturated Designs

A special class of supersaturated designs, called *marginally oversaturated designs* (MOSDs), in which the number of variables under investigation (k) is only slightly larger than the number of experimental runs (n), is presented in Deng *et al.* [13]. The construction method builds on the following theorem.

Theorem 2

1. Let $\mathbf{X} = [\mathbf{H}, \mathbf{v}]$, $\mathbf{w} = \mathbf{H}'\mathbf{v}$, where $\mathbf{H}$ is a Hadamard matrix of order n . Let R_1 be the number of

nonzero entries in $\mathbf{w}$. Then $r = R_1$, where r is the resolution rank of $\mathbf{X}$.

2. Let $\mathbf{X} = [\mathbf{H}, \mathbf{v}_1, \mathbf{v}_2]$ and $\mathbf{w}_1 = \mathbf{H}'\mathbf{v}_1$, $\mathbf{w}_2 = \mathbf{H}'\mathbf{v}_2$, where $\mathbf{H}$ is a Hadamard matrix of dimension n . Let $R_1 = \min[S(\mathbf{w}_1), S(\mathbf{w}_2)]$ and $R_2 = \min[S(b_1\mathbf{w}_1 + b_2\mathbf{w}_2)] + 1$, where $S(\mathbf{u})$ represents the number of nonzero elements in the vector $\mathbf{u}$ and b_1, b_2 can take on all possible values. Then $r = \min[R_1, R_2]$, where r is the resolution rank of $\mathbf{X}$.

For example, with $n = 12$, given $(1, \mathbf{x}_1, \dots, \mathbf{x}_{11})$ form a 12-run Hadamard matrix (as in Table 1), the optimal added columns $\mathbf{v}_1$ and $\mathbf{v}_2$ for MOSD from the theorem are $v_1 = (+ + + + + - - - - -)$ and $v_2 = (- + + + + - - - - -)$.

Three-Level Supersaturated Designs

Given a two-level orthogonal array $\mathbf{C}$ of size (n, m) , Yamada and Lin [5] provided a series of three-level supersaturated designs of the form $(N, K) = (3n, 4m)$ as follows.

$$\mathbf{D} = \begin{bmatrix} \phi^{12}(\mathbf{C}) & \phi^{12}(\mathbf{C}) & \phi^{13}(\mathbf{C}) & \phi^{23}(\mathbf{C}) \\ \phi^{23}(\mathbf{C}) & \phi^{13}(\mathbf{C}) & \phi^{23}(\mathbf{C}) & \phi^{12}(\mathbf{C}) \\ \phi^{31}(\mathbf{C}) & \phi^{23}(\mathbf{C}) & \phi^{12}(\mathbf{C}) & \phi^{13}(\mathbf{C}) \end{bmatrix} \quad (10)$$

where $\phi^{ab}(\cdot)$ is an operator which transforms the elements from -1 to a and from 1 to b on the matrix/vector in $(\cdot)$. Such a design can study $K = 4m$ factors in $N = 3n$ runs. It is shown in Yamada and Lin [5] that such designs have a relatively small value of $\text{ave } \chi^2$ as previously defined.

Multilevel Supersaturated Designs

Fang *et al.* [33] obtained a new class of multilevel supersaturated design by collapsing a U-type **uniform design** to an orthogonal array. This can be illustrated by the following example. Suppose that we extend the orthogonal design $\mathbf{L} = \mathbf{L}_9(3^4)$ and a generating U-type design $\mathbf{U} = \mathbf{U}(9, 9^2)$ to a S-design $S_9(3^8)$ by the collapsing method.

$$\mathbf{U} \oplus \mathbf{L} = \begin{bmatrix} 1 & 1 \\ 2 & 7 \\ 3 & 3 \\ 4 & 9 \\ 5 & 5 \\ 6 & 6 \\ 7 & 2 \\ 8 & 8 \\ 9 & 4 \end{bmatrix} \oplus \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 \\ 0 & 2 & 2 & 2 \\ 1 & 0 & 1 & 2 \\ 1 & 1 & 2 & 0 \\ 1 & 2 & 0 & 1 \\ 2 & 0 & 2 & 1 \\ 2 & 1 & 0 & 2 \\ 2 & 2 & 1 & 0 \end{bmatrix}$$

$$= \mathbf{X} = \begin{bmatrix} 0 & 0 & 0 & 0 & | & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & | & 2 & 0 & 2 & 1 \\ 0 & 2 & 2 & 2 & | & 0 & 2 & 2 & 2 \\ 1 & 0 & 1 & 2 & | & 2 & 2 & 1 & 0 \\ 1 & 1 & 2 & 0 & | & 1 & 1 & 2 & 0 \\ 1 & 2 & 0 & 1 & | & 1 & 2 & 0 & 1 \\ 2 & 0 & 2 & 1 & | & 0 & 1 & 1 & 1 \\ 2 & 1 & 0 & 2 & | & 2 & 1 & 0 & 2 \\ 2 & 2 & 1 & 0 & | & 1 & 0 & 1 & 2 \end{bmatrix}$$

where, the operation $\oplus$ is defined such that the i th block of $\mathbf{X}$ is essentially the matrix $\mathbf{L}$ by taking the row order of column i in matrix $\mathbf{U}$. Namely, the first block (the first four columns) of $\mathbf{X}$ is the original $\mathbf{L}$ and the second block (the last four columns) is formed by rearranging row vectors of $\mathbf{L}$ according to the order defined by the second column of $\mathbf{U}$. The crucial step of this collapsing method is how to choose the best U-type design $U(n, n')$ in the sense of minimizing any specific criterion (see [33]).

Conclusion

Since the study of *random balanced design* in late 1950s [1], the work of supersaturated design has been dormant until the appearance of Lin [15, 34]. The related work about supersaturated design is now much more mature, from better design construction to clearer understanding on design capability, to more reliable data analysis methods. In today's informatic era, as we face more and more variables/parameters, the use of supersaturated design is considered to be a relatively novel endeavor.

Supersaturated designs are very useful in early stages of the experimental investigation of complicated systems and processes involving many factors. They are not used for a terminal experiment. Knowledge of the confounding patterns makes possible the interpretation of the results and provides the understanding of how to plan the follow-up experiments.

Using supersaturated designs involves more risk than using designs with more runs. However, their use is far superior to other experimentation approaches such as subjective selection of factors or changing factors one at a time. The latter can be shown to have unresolvable confounding patterns, though such confounding patterns are important for data analysis and follow-up experiments. The success of a supersaturated design depends heavily on the "effect sparsity" assumption. Consequently, the projection properties

play an important role in designing a supersaturated experiment.

More and more researchers are benefiting from using computer power to construct designs for specific needs. Lin [34, 35] introduced the first computer algorithm to construct supersaturated designs. Nguyen [18] uses an exchange procedure to construct supersaturated designs and near-orthogonal arrays. Li and Wu [36] develop a so-called columnwise – pairwise exchange algorithm. Such an algorithm seems to perform well for constructing supersaturated designs by various criteria. Commercial statistical software for constructing supersaturated designs is also available, see for example, JMP.

Uniform Experimental Designs

Introduction

Because laboratory experiments and computer simulations cost time and money, researchers want to plan their experiments or computer simulations in a way that provides the most insight from a limited number of *runs*. This involves carefully choosing the values of the *factors*, also known as *explanatory variables*, *independent variables*, or *controllable parameters*, in order to understand how they affect the *response*, also known as the *dependent variable*. A given choice of factor values for each of the runs is called the *experimental design*. This article describes *uniform designs*, that is, experimental designs that sample the space of possible factor values, called the *experimental domain*, as evenly as possible.

Consider the problem of estimating the response (y) as a function of several controlled factors ($x_1, \dots, x_s$). We may have a model

$$y = f(x_1, \dots, x_s) + \varepsilon \quad (1)$$

The noise term ε is usually present in laboratory experiments, but may vanish in computer simulations. When the function f is unknown in physical experiments or f is too complicated in **computer experiments**, one would like to find a good approximation to the function f , denoted by $\hat{f}$. Let us consider two examples: one is a laboratory experiment from the chemical industry and another is a computer experiment arising in robotics.

Example 1: Chemical yield. A chemical experiment is conducted in order to find the manufacturing conditions that maximize the yield. The experimenter chooses four factors considered crucial to the production process: x_1 , the amount of formaldehyde (mol); x_2 , the reaction temperature ($^{\circ}\text{C}$); x_3 , the reaction time (h); and x_4 , the amount of potassium carbolic. The response y is the yield of the process. The experimenter does not know the model f relating the response and the four factors in equation (1) or even its form. The experimenter wants to find a good approximation to the model f via an experiment and the “best” four-factor-value combination in the sense of maximizing y .

Example 2: Robot arm. The movement trajectory of a robot arm is frequently used as an illustrative example in the **neural network** literature as well as in computer experiments. Consider a robot arm with m segments. The shoulder of the arm is fixed at the origin in the (u, v) plane. The segments of this arm have lengths L_j , $j = 1, \dots, m$. The first segment is at angle θ_1 with respect to the horizontal (u) axis. For $k = 2, \dots, m$, segment k makes an angle θ_k with segment $k - 1$. The end of the robot arm is at (u_m, v_m) , where

$$\begin{cases} u_m = \sum_{j=1}^m L_j \cos(\theta_1 + \dots + \theta_j) \\ v_m = \sum_{j=1}^m L_j \sin(\theta_1 + \dots + \theta_j) \end{cases} \quad (2)$$

and the response y is the distance $y = \sqrt{u_m^2 + v_m^2}$ from the end of the arm to the origin expressed as a function of $2m$ variables $\theta_j \in [0, 2\pi]$ and $L_j \in [0, 1]$. One wants to find a simple approximate model $y \approx \hat{f}(\theta_1, \dots, \theta_m, L_1, \dots, L_m)$ for the robot arm with m -segments as a surrogate for the true model f .

The above examples require the following:

1. **Design.** A design can help the experimenter discover valuable information about the underlying model. Because the form of the underlying model is typically unknown, a natural idea is to spread the experimental points as evenly as possible on the experimental domain.
2. **Modeling.** By various parametric or nonparametric model selection and **estimation** techniques, one wants to find a good approximation model $\hat{f}$ – also called a *metamodel* in the computer experiment literature.

The uniform design and other designs (e.g., the Latin hypercube design has been popular, *see Latin Hypercube Designs* for the details) can be used for the above purpose. The uniform design has been widely used in computer experiments (*see Computer Experiments; Latin Hypercube Designs*), physical experiments under model uncertainty and experiments with mixtures (*see Mixture Experiments*). It was proposed by Fang *et al.* [1–3]. Comprehensive reviews are given by Fang and Hickernell [4], Fang and Lin [5], Fang *et al.* [6], and Fang and Chan [7].

Experimental Design

The overall mean model has been used for developing theory and methodology of the uniform design: $y = \mu + h(x_1, \dots, x_s) + \varepsilon$. Let $\mathcal{P} = \{x_1, \dots, x_n\} \subset \mathcal{X}$ be an n run, s factor design. Suppose that the experimenter wants to estimate μ , the overall mean of the response y on the experimental domain $\mathcal{X}$. *The best design for this purpose is one whose empirical distribution approximates the uniform distribution.* This idea arose first in numerical integration methods for high-dimensional problems, called *quasi-Monte Carlo methods*, that were proposed in the early 1960s. The Koksma–Hlawka inequality (see Niederreiter [8] and Hickernell [9]) defines the discrepancy, $D(\cdot)$, or measure of uniformity, that quantifies the difference between the uniform distribution and the empirical distribution of the design. Designs with minimum discrepancy are called *uniform designs*.

The discrepancy is a Kolmogorov–Smirnov type goodness-of-fit statistic. Hickernell [10] showed that for estimating μ in the overall mean model the uniform design has optimal *average mean-square error* assuming random h and optimal *maximum mean-square error* assuming deterministic h . These facts mean that the uniform design is a kind of robust design (see **Robust Design**).

In fact, there are different forms of discrepancy, depending on the norm used to measure the difference between the uniform distribution and the empirical distribution of the design. The centered L_2 discrepancy (CD) proposed by Hickernell [11]

is a popular choice due to several nice properties, including invariance when the points are reflected about a plane through the middle of the domain.

Many authors have proposed constructions of uniform designs with various n and s . The notation $U_n(q^s)$ is for symmetric uniform designs and $U_n(q_1 \times \dots \times q_s)$ is for nonsymmetric uniform designs, very similar to the case for orthogonal design tables (see **Orthogonal Arrays**). For example, the first five columns of Table 1 represent a design $U_{15}(15^4)$. Constructions of uniform designs are made via the good-lattice-point method or integration lattices, digital nets, combinatorial methods, cutting methods as well as numerical search. A number of uniform designs can be found in the web site “<http://uniformdesign.org>”.

Even though the original theory of the uniform design is based on the overall mean model, such designs are useful for more general situations where the true model is unknown. Let us illustrate the method of the uniform design via Example 1. On the basis of familiarity with the process, the experimenter chooses the experimental region to be $[2, 6.2] \times [6, 55] \times [0.5, 7.5] \times [15, 85]$ and 15 equally spaced levels for each factor. Suppose that the amount of formaldehyde, the reaction temperature, the reaction time, and the amount of potassium carbolic are arranged according to the columns **1, 2, 3, 4** of $U_{15}(15^4)$ and use the real levels to replace levels 1, 2, $\dots$, 15 for each factor that forms four columns x_1, x_2, x_3, x_4 in Table 1. This results in a design with 15 level combinations. Their corresponding response,

Table 1 $U_{15}(15^4)$, related design and responses

Number	1	2	3	4	x_1	x_2	x_3	x_4	y
1	9	1	4	10	4.4	6	2	60	0.0835
2	11	14	5	5	5	51.5	2.5	35	0.1847
3	10	7	10	1	4.7	27	5	15	0.1121
4	3	12	3	2	2.6	44.5	1.5	20	0.1121
5	13	10	2	13	5.6	37.5	1	75	0.1663
6	5	4	8	15	3.2	16.5	4	85	0.1522
7	2	2	12	6	2.3	9.5	6	40	0.0046
8	12	5	14	11	5.3	20	7	65	0.2445
9	1	8	6	12	2	30.5	3	70	0.1436
10	7	6	1	7	3.8	23.5	0.5	45	0.1138
11	4	15	9	9	2.9	55	4.5	55	0.1357
12	14	3	7	3	5.9	13	3.5	25	0.1618
13	6	9	15	4	3.5	34	7.5	30	0.0640
14	15	11	11	8	6.2	41	5.5	50	0.2014
15	8	13	13	14	4.1	48	6.5	80	0.2618

that is, chemical yield, is given in the last column of the table. The larger the y value, the higher the output.

Modeling

On the basis of the experimental data one wishes to find a metamodel to fit the data. This metamodel should approximate the true model well, where the true model is known in computer experiments and may be unknown in some physical experiments. There are many modeling techniques in the literature, such as linear, quadratic, polynomial or nonlinear regression, **spline**, kriging, the Bayesian approach, and so on. The reader may refer to Fang *et al.* [6] and references therein for details.

For linear regression models

$$y = \beta_1 + \beta_2 g_2(x) + \cdots + \beta_p g_p(x) + \varepsilon \quad (3)$$

one usually applies model selection techniques to decide the factors, x_j , to include in the model, and the forms of the terms, $g_l(x)$, involving those factors. To estimate the regression coefficient, $\beta = (\beta_1, \dots, \beta_p)^T$, the regression matrix $\mathbf{G}(\mathbf{X}) = (g_l(x_i))_{i,l=1}^{n,p}$ must have full rank, that is, linearly independent columns, and this depends on the design $\mathbf{X} = \{x_1, \dots, x_n\}$.

For the data in Table 1 we might try many modeling methods to find metamodels and then choose the best one among these candidate models. If we employ a centered quadratic regression model with model selection to choose the significant terms, we obtain

$$\begin{aligned} \hat{y} = & -0.103 + 0.0287x_1 + 0.00136x_2 + 0.00295x_3 \\ & + 0.00146x_4 + 0.000429(x_1 - 4.1)^2 \\ & + 0.00509(x_1 - 4.1)(x_3 - 4) \\ & + 0.000499(x_3 - 4)(x_4 - 50) \end{aligned} \quad (4)$$

with $R^2 = 0.91$ and error standard deviation $\hat{\sigma} = 0.0283$. The maximum of $\hat{y}$ on the experimental domain according to this model occurs at $x_1 = 6.2$, $x_2 = 55$, $x_3 = 7.5$, $x_4 = 85$ and the maximum $\hat{y}$ value is 0.40779, which is much larger than the maximum value among 15 runs, $y_{15} = 0.2618$. The uniform design with linear regression modeling suggests the optimal level-combination, which should then be verified by some additional experiments.

Applications and Discussion

The uniform design has a number of good statistical properties. In addition to its optimality for the overall mean model mentioned above, Xie and Fang [12] pointed out that the uniform measure is admissible and minimax under a nonparametric regression model. Hickernell and Liu [13] considered the efficiency and robustness of uniform experimental designs for linear regression models. They found that “Although it is rare for a single design to be both maximally efficient and robust, it is shown here that uniform designs limit the effects of **aliasing** to yield reasonable efficiency and robustness together.”

The uniform design provides flexibility in design and modeling for the user and can be used for complicated nonlinear models. The uniform design is robust against model specification (*see Robust Design*). Although the number of levels in a uniform design is typically equal to the number of runs, a smaller number of levels can be used by collapsing adjacent levels into one level. The uniform design can be applied to experiments with qualitative and quantitative factors and it can also be used for experiments with mixtures. Many products are formed by mixtures of several ingredients, for example, building construction concrete consists of sand, water, and one or more types of cement. Designs for deciding how to mix the ingredients have played an important role in various fields such as chemical engineering, rubber industry, and material and pharmaceutical engineering. Cornell [14] gave a comprehensive treatment of the design and analysis of experiments with mixture (*see Mixture Experiments*). The uniform design can be also applied to such experiments even with some constraints (*see Fang and Yang [15]*).

There are close relationships among the **fractional factorial** design, the supersaturated design (*see Supersaturated Designs*) and the uniform design. For example, various discrepancies (centered L_2 discrepancy, wraparound L_2 discrepancy, and discrete discrepancy) can be used for comparing orthogonal/supersaturated designs and detecting nonisomorphic orthogonal designs.

KAI-TAI FANG AND FRED J. HICKERNELL

Box–Behnken Designs

Historical Background

The topic of experimental designs for second-order models is one that has received a great deal of attention in the literature since Box and Wilson's [1] inception of response surface methodology (*see Response Surface Methodology*). In order to estimate a second-order term for a given factor, there must be at least three levels of that factor in the experimental design. A natural design choice for estimating a quadratic model is the 3^k factorial design (*see Factorial Experiments*) in which k denotes the number of experimental factors. However, when k becomes moderately large, the 3^k factorial design may involve an impractical number of design points. In order to reduce the number of design points, Finney [2] considered fractional factorial (*see Fractional Factorial Designs*) subsets of the complete 3^k design. Box and Behnken [3] defined a *redundancy factor* equal to the number of design points divided by the number of model parameters. They pointed out that for situations in which the experimental error variance is not so large as to require large numbers of observations to obtain necessary precision of model parameters, designs having small redundancy factors are desirable. Applying the redundancy factor to a one-third replicate of a 3^5 factorial design when the interest is in estimating 21 model parameters (intercept, 5 linear terms, 10 two-factor interactions, and 5 pure quadratic effects) the redundancy factor is $81/21 \approx 3.9$. In order to reduce the redundancy factor, Box and Behnken [3] proposed the class of designs which are now commonly referred to as *Box–Behnken designs*. Henceforth, we refer to the Box–Behnken design as a *BBD*.

Box–Behnken Design Construction

BBDs represent a family of three-level designs that are highly efficient for estimating second-order response surfaces. The formulation of these designs is accomplished by combining two-level factorial designs (*see Factorial Experiments*) with incomplete block designs (*see Block Designs, Incomplete*) in a specific manner. This formulation is best illustrated *via* an example. Consider the balanced incomplete block design with three treatments and three

blocks, each of size two, given in Table 1. The BBD in three factors is obtained by combining this incomplete block design with 2^2 factorial designs which involve all combinations of the three factors. The two asterisks in every row of the balanced incomplete block design of Table 1 are replaced by the two columns of the 2^2 factorial design in the corresponding factors. Wherever an asterisk does not appear, a column of 0's is inserted. The resulting three-factor BBD is given in Table 2. Note that the last row in the design is a vector of n_c center runs.

Although many BBDs can be constructed by combining factorial designs with balanced incomplete block designs, sometimes the construction must involve a partially balanced incomplete block design instead. In the construction this implies that not every factor will occur in a two-level factorial structure the same number of times with every other factor. As an example, consider $k = 6$ factors and the $N = 48 + n_c$ run design provided in Table 3. Here, each row of the design matrix involves eight design points and the ± 1 notation indicates a 2^3 factorial structure among the corresponding pairs of variables. Note the partial

balance by observing that X_1 occurs with X_4 twice (rows 1 and 4) whereas X_1 occurs with X_2, X_3, X_5 , and X_6 only one time. See Myers and Montgomery [4, pp. 345–347] for more details regarding the construction of BBDs.

Characteristics of the Box–Behnken Design

Upon observing the design in Table 2, it is evident that the BBD is comparable to the central composite design (CCD; *see Central Composite Designs*) in terms of design size. The CCD for $k = 3$ factors contains $14 + n_c$ runs and the BBD contains $12 + n_c$ runs. The CCD and the BBD are also quite comparable in size for larger numbers of factors. Borkowski [5, 6] develops prediction variance properties of the CCD and BBD and then uses variance dispersion plots (see Giovannitti-Jensen and Myers [7]) to compare the two designs in terms of minimum, maximum, and average spherical prediction variances. He notes that the two designs possess good prediction variance properties, especially when a sufficient number of center runs are utilized. In terms of other alphabetic optimality (*see Optimal Design; Assessment of Experimental Designs*) efficiencies for the BBD, Lucas [8] reports D-, G-, A-, and E-efficiencies for varying numbers of center runs. Borror *et al.* [9] compare the BBD to the CCD for estimating the slope variance when one is in the robust design (*see Robust Design*) setting. Davison [10, pp. 91–102] compares the CCD and BBD in terms of prediction variance properties and D-efficiency within the context of a split-plot **randomization** (*see Split-Plot Designs*) scheme. Parker *et al.* [11, 12] provide a generalized derivation of equivalence conditions for the BBD and CCD when split-plot randomization is present.

Other than offering appealing prediction variance properties as well as small design sizes, the BBD also

displays other desirable characteristics. Whittinghill [13] discusses the robustness of BBDs to the unavailability of data. The BBD generally allows sufficient information for testing **lack of fit**, it is often close to being rotatable (*see Rotatable Designs and Rotatability*), and the design is often suitable for orthogonal blocking (*see Blocking*). To illustrate the degrees of freedom (df) for lack of fit as well as suitability for orthogonal blocking, consider the BBD for $k = 4$ factors with $n_c = 6$ center runs (*see Center Points*), which is provided in Table 4. The ± 1 notation here indicates the 2^2 factorial structure among the corresponding pairs of variables. Note that the vectors of 0's in the rows which contain factorial points are 4×1 vectors whereas the vectors of 0's in the last row of each block are 2×1 vectors. The design in Table 4 is composed of $N = 24$ factorial points + 6 center runs. Ignoring blocks and assuming a quadratic model (intercept, four linear main effects (*see Main Effects*), six two-factor interactions (*see Interactions*), and four pure quadratics), there are 10 df for lack of fit and 5 df for pure error. For a catalog of BBDs with up to $k = 10$ factors and possible orthogonal blocking schemes, see Box and Behnken [3].

A final important characteristic of BBDs is that their design region is spherical. Figure 1 displays the design points of the $k = 3$ BBD from Table 2. Note that all of the points lie on the edges of the cube and are equidistant (distance = $\sqrt{2}$ units) from the design center. Although the BBD provides good coverage of the cube, there are no points on the corners and the BBD is not a good choice in situations when the experimenter is interested in predicting at the corners. When the experimenter desires more complete coverage of the cube, a face-centered CCD is preferred to the BBD.

Example

Consider the following example from Myers and Montgomery [4, p. 347] concerning the production of a particular polyamide resin. One step in the production involves the addition of amines. It was felt that the manner of addition has an impact on the molecular weight distribution of the resin. Three factors were under consideration: temperature at the time of addition (X_1 , °C), agitation (X_2 , rpm), and rate of addition (X_3 , min^{−1}). The viscosity of the resin (y) was recorded as an indirect measure of molecular weight. The BBD used, along with the coded levels of the factors and corresponding resin values, is provided in Table 5.

Notice that this design corresponds to the three-factor BBD ($n_c = 3$) provided in Table 2, but with the run order randomized. A full second-order model (intercept, three linear main effects, three pure quadratics, and three two-factor interactions) was fit and the results are found in Tables 6 and 7.

Note that with only 15 experimental runs, the BBD

allows for **estimation** of all model coefficients, 3 df for lack of fit and 2 df for pure error. The lack-of-fit test suggests that a quadratic model is sufficient. Further details of the analysis of this example can be found in Myers and Montgomery [4, pp. 348–350].

Conclusions

The BBD is a popular design for experimenters who wish to fit a second-order response surface model. The design region is spherical and should only be used in situations where the experimenter is not interested in predicting at the corners of a cuboidal region. The design is not only economical in terms of design runs, but it also possesses good prediction variance properties when conducted in either the completely randomized setting or a split-plot setting. Box and Behnken [3] provide a catalog of BBDs for up to $k = 10$ factors along with possible orthogonal blocking schemes. The popularity of the BBD has been recognized by major statistical software packages such as SAS JMP, MINITAB, and Design Expert and these designs can be easily constructed using these software packages.

Center Points

Introduction

In an experimental design with k quantitative factors, it is customary to code the levels of each factor so that the minimum level is -1 and the maximum level is 1 . A *center point* is an observation taken at the design point $(x_1, x_2, \dots, x_k) = (0, 0, \dots, 0)$ that is located in the center of the design region. The primary reasons that center points have been included in experimental designs are to provide an estimate of pure experimental error, to allow for tests of **lack of fit** for first-order **response surface** design and for tests of curvature in 2^k designs, and to ensure orthogonal **blocking** and uniform precision for second-order response surface design. Descriptions of these statistical applications of center points will be reviewed. First, several comments related to testing for model lack of fit will be given.

Decisions and predicted responses are based on a fitted model. Therefore, it is important to assess the adequacy of the fitted model because an incorrect model can lead to conclusions that are erroneous, and, in particular, lead to unreliable predicted responses. A statistical test for checking the adequacy of a fitted response surface model is called a *lack-of-fit test* of the fitted model. When we say that a proposed response surface model is “lacking in fit”, we are implying that the model is inadequate because it does not contain enough terms because either (a) there exist one or more factors that are omitted from the proposed model but affect the response of interest or (b) one or more higher-order terms involving factors already in the proposed model are needed to adequately explain the relationship between the response and these factors [1].

The following two design conditions must be met to perform a test for the adequacy of the fitted response surface model (i.e., testing for no lack of fit): (a) the number of distinct design points must exceed the number of terms in the fitted model and (b) the design must contain replicated points that will provide an estimate of the experimental error variance that does not depend on the form of the fitted model. When these two conditions are satisfied, the error **sum of squares** (SSE) can be partitioned into two component sources of variation: the variation associated with the replicated points (referred to as the

pure error sum of squares and denoted SS_{PE}) and the variation attributable to model lack of fit (denoted SS_{LOF}). Thus, $SSE = SS_{PE} + SS_{LOF}$. Although condition (b) can be satisfied by having at least two replicates for one or more design points, it is common to use several center points as the replicates [1].

Center Points and Two-Level Response Surface Designs

Two-level response surface designs are often used when the researcher is interested in fitting either a first-order [2] or interaction [3] response surface model, where

$$y = \beta_0 + \sum_{i=1}^k \beta_i x_i + \epsilon \quad (\text{First-order model}) \quad (1)$$

$$y = \beta_0 + \sum_{i=1}^k \beta_i x_i + \sum_{i < j}^k \beta_{ij} x_i x_j + \epsilon \quad (\text{Interaction model}) \quad (2)$$

Popular two-level designs are the Plackett–Burman designs [4] and the low-resolution 2^{k-p} **fractional factorial** designs [5] for the first-order model and the 2^k full factorial designs [6] and high-resolution 2^{k-p} fractional factorial designs for the second-order model. Note that these designs cannot detect lack of fit due to quadratic x_i^2 terms.

For a 2^k design, let n_f be the number of factorial design points. To test for curvature (i.e. the presence of x_i^2 terms in the true model) n_c center points are included in the design. Let $\bar{y}_f$ and $\bar{y}_c$ be the response means for the factorial and center points, respectively. Thus, if curvature is not present, then a first-order or interaction model may adequately model the response surface, and we would expect that $\bar{y}_f \approx \bar{y}_c$. Thus, if the difference $\bar{y}_f - \bar{y}_c$ is large, we conclude curvature is present.

If the second-order response model is considered as an alternative model, then the null and alternative hypotheses for the test for curvature are $H_0 : \sum_{i=1}^k \beta_{ii} = 0$ and $H_a : \sum_{i=1}^k \beta_{ii} \neq 0$. The sum of squares for curvature based on the contrast $\bar{y}_f - \bar{y}_c$ is $SS_{\text{curv}} = [n_f n_c (\bar{y}_f - \bar{y}_c)^2] / (n_f + n_c)$. Because it has a single degree of freedom, $MS_{\text{curv}} = SS_{\text{curv}}$, and it may be compared to MS_{PE}

2 Center Points

Table 1 A test for curvature

Uncoded		Coded		Yield	$n_f = 4 \quad \bar{y}_f = 44.3$
ξ_1	ξ_2	x_1	x_2	y	
35	150	-1	-1	43.8	
35	160	-1	1	44.6	
45	150	1	-1	43.9	
45	160	1	1	44.9	$n_c = 5 \quad \bar{y}_c = 44.9$
40	155	0	0	44.6, 45.0, 44.8, 45.2, 44.9	

to test for curvature (where the pure error $MS_{PE} = SS_{PE}/(n_c - 1)$ is calculated from the replicated center points). Note that although the test may indicate that curvature is present, we do not have estimates for $\beta_{11}, \dots, \beta_{kk}$. One should augment the design with additional points to allow for **estimation** of these model parameters [7].

Numerical Example suppose the goal is to determine the operating conditions for two process variables (mixing time ξ_1 and oven temperature ξ_2) that maximize the process yield y . The process is currently operating with a mixing time of 40 min and a temperature of 155 °F. It was determined that the experimental region should be from 35 to 45 min for mixing and from 150 to 160 °F for oven temperature. A completely randomized 2^2 design with five center points with process variables mixing time ξ_1 and oven temperature ξ_2 was run. A test of curvature is performed assuming an interaction model. The values of the process yield (y) response are given in Table 1.

Then, $SS_{\text{curv}} = MS_{\text{curv}} = [(4)(5)(44.3 - 44.9)^2]/9 = 0.8$ and $MS_{PE} = 0.05$. Thus, $F = 0.8/0.05 = 16$, and the p value based on a $F(1, 4)$ distribution is 0.0161 suggesting the presence of curvature.

Another important issue regarding two-level designs arises when no design points are replicated. Specifically, the unreplicated design will not produce data that yields an independent estimate of the experimental error variance. For example, when a first-order or interaction model is fitted, then the SSE contains variation attributable to both experimental error and to the lack of fit of that model. Significant lack of fit of a first-order model will occur when the model is fitted over a range of factor levels where terms of higher order are needed to adequately model the response [1]. In the case of a saturated first-order design, it not

possible to test for lack of fit of the first-order model.

The properties of a two-level design, however, may change once it is augmented with replicated design points. For an orthogonal two-level design, an equal number of replications for each design point is needed to preserve the orthogonality property. Unfortunately, the cost of such replication may be prohibitive. A cost-efficient alternative is to augment an unreplicated design with center point replications. This enables the experimenter to obtain an independent estimate of the experimental error while maintaining the orthogonality of the design. It also allows for traditional model lack-of-fit tests to be performed [1]. Estimates resulting from a 2^k design also remain unaffected by the addition of replicates at the center of the design region [7].

Center Points in Second-Order Response Surface Designs

Two of the designs most often used to fit second-order response surface models are the **central composite** designs (CCDs) [8] and the Box–Behnken designs (BBDs) [9]. CCD points are composed of factorial points from a 2^k or 2^{k-p} design, axial points, and center points, while BBD points are constructed from **incomplete block** designs [10] to which center points are added. Information regarding the use of center points in second-order response surface designs can be found in [11–14].

The CCD is a very efficient design for fitting the second-order response surface model. The factorial points form a design that minimizes the variances of the estimated coefficients in a first-order or interaction model. The center points provide information about the existence of curvature, and if curvature is

present they also contribute toward the estimation of quadratic terms.

For a k -factor CCD, the experimenter has the flexibility to control both the axial point distance α and the number of center points n_c . While choice of α depends to a great extent on the regions of operability and interest, the choice of n_c affects prediction variances in the region of interest. If $\alpha = \sqrt{k}$ and $n_c = 0$, then the CCD would be a spherical design (i.e., all design points are equidistant from the center of the design region). The experimental design matrix would be singular, meaning the second-order model parameters cannot be estimated. Thus, n_c must be ≥ 1 when $\alpha = \sqrt{k}$ to avoid the singularity and allow estimation of all model parameters. In addition, the use of center points also provides reasonable stability for the prediction variance function in the design region. Hence, inclusion of center points in a CCD is very beneficial. Options regarding n_c and α were studied in [11], and it was concluded that the best CCDs should have $\alpha \approx \sqrt{k}$ and $2 \leq n_c \leq 5$ [7].

The spherical nature of the BBD, combined with the fact that the designs are rotatable or near rotatable [15], suggests that center points should be included in the design. When $k = 4$ or 7, BBDs are spherical designs making center points necessary to avoid singularity of the design matrix. Spherical or nearly spherical designs require three to five center points to avoid a severe imbalance in the prediction variance through the design region.

In general, in an unblocked response surface design, the number of center points can be used to control various properties of the design matrix X . Under certain conditions, the number of center points can make X have uniform precision (or have near-uniform precision). A design has *uniform precision* if the prediction variance at the center of the experimental region and at a unit distance away from the center are equal.

The number of center points can also be chosen to cause a rotatable CCD to have the uniform (or near-uniform) precision property. Setting n_c to be the integer closest to $\lambda_4(\sqrt{F} + 2)^2 - F - 2k$ yields a uniform precision rotatable design. For an N -point CCD, λ_4 is the constant mixed fourth-order design moment $(1/N) \sum_{u=1}^N x_{ui}^2 x_{uj}^2$ for any pair of design factors $i \neq j$. Values of λ_4 can be found in [1]. If it is desired for a CCD to be orthogonal as well as rotatable, it is possible to choose α and n_c to

achieve both properties. To achieve the rotatability, we only need to choose α such that $\alpha^4 = F$ where F is the number of factorial points in the CCD. To achieve orthogonality, n_c is the integer closest to $4\sqrt{F} + 4 - 2k$ [1].

There are many practical situations in which the experimenter specifies strict minimum and maximum levels for the design factors. That is, the region of interest and the region of operability are the same, and the resulting design region is a cube. By setting $\alpha = 1$, we have a CCD in the cube which is referred to as a face-center cube design (FCCD). The recommendations for the number of center points differ between FCCDs and CCDs in spherical design regions. For a FCCD, only one or two center points are sufficient to provide reasonable stability to the prediction variance. Thus, the stability of the prediction variance is much more sensitive for a CCD in a spherical region than for an FCCD in a cuboidal region [7].

JOHN J. BORKOWSKI

Central Composite Designs

Fitting a Response Surface to Data

Suppose an experimenter wishes to examine several predictor variables $x_1, x_2, \dots, x_k$, in order to determine their effects, individual or combined, on a response variable y . A standard way of proceeding is to decide on n (say) specific combinations of levels of the x 's ($x_{1u}, x_{2u}, \dots, x_{ku}$), $u = 1, 2, \dots, n$; at each of these, the value of the response y (y_u for the u th experiment) will be measured. These n experiments, or *runs* as they are usually called, form the *experimental design* or simply the *design*. Further analysis of the experimental results arising from performing the design usually consists of fitting a model, often of polynomial form, to the data, using the least-squares method of regression analysis, and then assessing what the computations reveal. The fitted model could be first order (planar), for example:

$$\hat{y} = b_0 + b_1x_1 + b_2x_2 + \dots + b_kx_k \quad (1)$$

where each x has only a linear effect; or could be second order (quadratic)

$$\begin{aligned} \hat{y} = & b_0 + b_1x_1 + b_2x_2 + \dots + b_kx_k \\ & + b_{11}x_1^2 + b_{22}x_2^2 + \dots + b_{kk}x_k^2 \\ & + b_{12}x_1x_2 + b_{13}x_1x_3 + \dots + b_{k-1,k}x_{k-1}x_k \end{aligned} \quad (2)$$

where all possible second-order terms (power 2, squares and cross-products) have been added to equation (1). These equations are called *fitted equations*, *fitted models*, or *fitted surfaces*. The *hat* (caret) over the y indicates the *predicted value* of y . The b 's are numbers, estimates obtained via the least-squares method, of the *true but unknown* regression coefficients. The fitted models provide (in many cases) a plausible representation of, or an approximation to, the true surface. The models shown above simply represent first- and second-order Taylor's series expansions of a general functional form and are thus expected to embody the main features of the variations in the response. This is often true in practice. The first step in the process is thus to decide what sort of design should be employed (see **Response Surface Methodology**.)

First-order Designs

The simplest good choice to fit a first-order model, equation (1), would be a full two-level factorial or a fractional factorial type design of resolution III or IV (see **Factorial Experiments; Fractional Factorial Designs; Orthogonal Arrays**). A resolution III design would associate (some or all) main effects with two-factor interactions; a resolution IV design would associate (some or all) main effects with three-factor interactions and two-factor interactions with other two-factor interactions. The philosophy here would be that only the main effects (the b_i) were likely to be important in the exploratory phases of an investigation.

Coding the Experimental Conditions

Two levels of a predictor variable can always be coded to -1 and $+1$. For example, if two temperatures $T = 125$ and 175°C were to be used, the coding $(T - 150)/25$ would achieve the coded levels. Note that the coded level 0 (here 150°C) would be the center of the range selected. Often, the center of the entire design would represent the *current best set of conditions within the experimental region* and the experiment would attempt to find the best manner of moving outward to improve the response. With two variables, temperature and pressure say, the coded levels of a 2^2 design would be $(x_1, x_2) = (-1, -1), (-1, 1), (1, -1),$ and $(1, 1)$ and this design would provide enough information to fit a first-order model (a plane) in the two-dimensional experimental space. If the first-order surface were deemed to be adequate, subsequent follow-up analysis would usually consist of following the path of steepest ascent, that is, the straight line in the experimental space in which the predicted response improves the fastest. Often such an analysis would provide rapid improvement in the response and allow the experimenter to move to a better region of the experimental space.

The Central Composite Second-order Design

To fit a second-order model, at least three levels of each x_i must be chosen to permit detection of curvature in the response. A popular and practical

2 Central Composite Designs

design choice, which can be found in many published experimental presentations, is the so-called central (i.e., centrally located about the coded design origin) composite design, which provides three, four, or five levels. A composite design consists of three parts:

1. A “cube” part, that is, a two-level n_c points portion, $(\pm 1, \pm 1, \dots, \pm 1)$, usually of resolution IV or higher (which means that no **main effect** is aliased with any two-factor interaction); plus
2. a “star” part, consisting of $2k$ axial points of the forms $(\pm\alpha, 0, 0, \dots, 0)$, $(0, \pm\alpha, 0, \dots, 0)$, $(0, 0, \pm\alpha, 0, \dots, 0)$, $\dots$, $(0, 0, 0, \dots, 0, \pm\alpha)$, where α will be chosen to match the experimental goals; plus
3. n_0 center points $(0, 0, \dots, 0)$ (*see Center Points*).

In general, this design uses five levels of each predictor variable. Without center points, there are only four levels $(-\alpha, -1, 1, \alpha)$. The omission of center points is unusual, because there would then be no comparison with the current best levels mentioned earlier. When $\alpha = 1$, the general design can be described as a *face-centered central composite design* and has only three levels $(-1, 0, 1)$. In this case, center points must be included so that the full second-order model can be fitted.

Figure 1, reproduced from [1, Chapter 9], shows a composite design in $k = 3$ dimensions with $n_0 = 2$ center points and $\alpha = 2$; response values are shown attached at the various experimental locations. Each factor is at five levels, namely $(-2, -1, 0, 1, 2)$. The statistical analysis of this particular example is described below.

Choice of the Star Distance α

The value of α selected for a particular investigation will depend on the circumstances. Clearly, the width 2α must lie within the chosen experimental range of the factors. A good general question to ask first in considering a choice for α is “What values of α provide design points that cover the experimental region in a way that makes the experimenter feel comfortable?”

By an appropriate choice of α , any second-order central composite design can be made *rotatable*, which means that, in the coded coordinates, information obtained from the design, as measured by $V(\hat{y})$, the variance of the fitted value function, is equally

accurate at all points that lie the same distance from the center of the design (*see Rotatable Designs and Rotatability* for more detail). Rotatability is desirable but not mandatory. Nevertheless the rotatable α values would be useful ones to keep in mind as a starting point. The appropriate values for a selected “single cube plus single star” central composite design are shown in Table 1.

The asterisk indicates that a half fraction of the 2^k design is being used. Adding center points does not affect rotatability.

It would be unusual to choose $\alpha < 1$, unless the factorial levels had been set far too wide in the cube portion. Moreover, such a narrow choice would tend to make the design “less rotatable”.

A composite design is often performed sequentially in two parts. The first part would usually consist of the cube portion plus some center points, thus enabling a first-order model to be fitted and also providing a test for lack of planar fit by comparing the average response at the center point with the average response at the factorial points and dividing by the appropriate **standard error** to create a testable *t*-statistic. A significant value indicates the need to fit a second-order model. Addition of the star portion plus (often) further center points would allow a full second-order model to be fitted using the entire set of data. In such cases, the addition to the model of a *blocking variable* might be desirable if it were felt that the two parts of the experimental design would each occur at a different overall level of response (*see Blocking*). This would be a sensible precaution if the two parts of the design were performed in different weeks, or the operators were different, or two individual reactors were used. Note that performing center points in *both* blocks and comparing the two corresponding sets of response values gives *direct* information on the possible differences between blocks.

Another possible choice of α would be the value that provides orthogonal blocking when the design is performed in more than one block. This is somewhat difficult to explain briefly. One would first need

Table 1 Values of α that make single cube plus single star second-order central composite designs rotatable

k :	2	3	4	5	5*	6	6*
n_c :	4	8	16	32	16	64	32
α :	1.414	1.682	2	2.378	2	2.828	2.378

Figure 1 A central composite design in three dimensions ($k = 3$). (a) Cube portion $(\pm 1, \pm 1, \pm 1)$. (b) "Star" portion $(\pm \alpha, 0, 0)$, $(0, \pm \alpha, 0)$, $(0, 0, \pm \alpha)$ with $\alpha = 2$. (c) Center points $(0, 0, 0)$. (d) Cube, plus star, plus two center points with response data values attached

to decide how many blocks to use, then which runs to put in which block, and then how the levels for the blocking variable columns would be chosen. The worked example below has an α value of 2 that achieves orthogonal blocking; the blocking variable column used there, with -1 's and 1 's, is orthogonal to all the columns in the $\mathbf{X}$ matrix generated by the second-order model. (This design is thus not rotatable, which would require $\alpha = 1.682$.) An example in which orthogonal blocking was achieved by a choice of $\alpha = 1.2872$ is mentioned in [2, p. 290]. Second-order central composite designs have been in popular use for over half a century [3], and for excellent reasons. Their theoretical and practical properties make them rank high in comparison with other

suggested designs, using several different criteria (*see Optimal Design*).

Analysis of the Data

The particular experiment of our example was performed sequentially, but not exactly in the way described above. There *were* two blocks, performed in different weeks, but the first consisted of just the cube portion with no center points added, while the second block consisted of the star, at a coded distance of two units from the origin, plus two center points. This had the advantage of providing the same number of runs, namely eight, per block but failed to provide a direct block-to-block center points comparison

4 Central Composite Designs

Table 2 First (runs 1–8) and second (runs 9–16) blocks of experimental data

Number	x_1	x_2	x_3	x_B	y
1	−1	−1	−1	−1	25.74
2	1	−1	−1	−1	48.98
3	−1	1	−1	−1	42.78
4	1	1	−1	−1	35.94
5	−1	−1	1	−1	41.50
6	1	−1	1	−1	50.10
7	−1	1	1	−1	46.06
8	1	1	1	−1	27.70
9	0	0	0	1	57.52
10	0	0	0	1	59.68
11	−2	0	0	1	35.50
12	2	0	0	1	44.18
13	0	−2	0	1	38.58
14	0	2	0	1	28.46
15	0	0	−2	1	33.50
16	0	0	2	1	42.02

at the same levels. The planar model (1) was fitted to the first set of data when it was collected (see observations 1–8 in Table 2), giving rise to the fitted equation (3).

$$\hat{y} = 39.85 + 0.83x_1 - 1.73x_2 + 1.49x_3 \quad (3)$$

The four estimated coefficients 39.85, 0.83, 1.73, and 1.49 all have standard errors of 4.16 based on the residual mean square of $s^2 = 138.3$, revealing a puzzling picture of a very significant mean level and non-significant first-order effects. Two statistical features provide added clarification. If the interaction terms in x_1x_2 , x_1x_3 , x_2x_3 are added to the model, all of their estimated coefficients (values -7.13 , -3.27 , -2.73 respectively) are much larger than the linear effects and, moreover, the estimate 39.85 in equation (3) is actually an estimate of $\beta_0 + \beta_{11} + \beta_{22} + \beta_{33}$ where $\beta_{11}x_1^2 + \beta_{22}x_2^2 + \beta_{33}x_3^2$ are the *pure quadratic* terms that would be added to the model if a full second-order (quadratic) model were appropriate. At the present stage of analysis, we do not have enough data to estimate a full second-order model, however. A logical next step then is to add a “star” set of points (six points for three dimensions) plus a couple of center points, as mentioned earlier. The entire set of data appears in Table 2, together with the addition of a blocking variable denoted by x_B . The latter is allotted the values -1 for the first block of data and 1 for the second block. Actually,

any two distinct numbers would suffice, for example $(0, 1)$, but the specific choice of $(-1, 1)$ has the advantage, in this particular design, of making the blocks column orthogonal to all the other columns needed to fit a full second-order model, which means that the blocking effect can be cleanly separated from the estimated model effects, both numerically and in the subsequent analysis of variance table. Such orthogonality is worth seeking and is often achievable, depending on the specific design used (see **Blocking**).

The second-order model fitted to the complete set of 16 runs takes the form

$$\begin{aligned} \hat{y} = & 57.31 + 1.50x_1 - 2.13x_2 + 1.81x_3 \\ & - 4.69x_1^2 - 6.27x_2^2 - 5.21x_3^2 - 7.13x_1x_2 \\ & - 3.27x_1x_3 - 2.73x_2x_3 + 1.29x_B \end{aligned} \quad (4)$$

and the corresponding analysis of variance table appears as Table 3.

Viewing the entire set of results, we conclude that there is no **lack of fit**, that it is useful to remove a block component of the variation, and that the full second-order model is needed to provide a useful representation of the fitted second-order surface. A “ridge analysis” of the fitted surface can be found in (**Ridge Analysis in Experimental Design**).

Central Composite Designs for Higher Dimensions

For higher dimensions, $k \geq 5$, the number of runs needed for a central composite design can be reduced by choosing the “cube” part to be a *fractional* factorial rather than a full factorial. In order that

Table 3 The analysis of variance table for the experiment

Source of variation	df	SS	MS	$F^{(a)}$
b_0	1	27079.99	—	—
Blocks, orthogonal to model	1	26.63	26.63	8.94
First order, given b_0	3	161.01	53.67	18.01
Second order, given first, b_0	6	1290.61	215.10	72.18
Lack of fit	4	12.60	3.20	1.37
Pure error	1	2.33	2.33	—
Total	16	28573.17	—	—

^(a) Using $s^2 = (12.60 + 2.33)/(4 + 1) = 2.98$ as denominator except for lack of fit F test

all main effects and two-factor interactions (essentially the b_i and the b_{ij}) may be separately estimated, the fractional factorial must usually be of resolution V or higher. Resolution V ensures that main effects are aliased, or associated, with four-factor interactions, at worst, and that two-factor interactions are aliased or associated with three-factor interactions, at worst (see **Fractional Factorial Designs**). In much experimental work, it is typically anticipated (initially, at least, until evidence arises to the contrary) that three- and four-factor interactions are very unlikely to occur. A regression-type extra **sum-of-squares**, lack-of-fit test will allow these sorts of assumptions to be tested; further runs can then be added if required to estimate additional parameters. For tables of central composite designs, see, for example [[1], Chapter 15], [[4], pp. 508–517], and [[5], p. 431]. For more illustrative worked examples, see [[1], Exercises 11.5–11.7, 11.9, 11.16, and 11.18–11.20 together with their corresponding solutions].

Other Composite Design Variations

Other variations on composite designs are the following:

1. Central composite designs that consist of more than two pieces, for example, one cube plus two stars. The two stars could be a doubled star, sharing the same α value, or they could have different α values. Or the cube could be doubled, perhaps using different sizes. The coded dimensions could be chosen to provide rotatability and/or orthogonal blocking, as feasible, and so on.
2. Noncentral composite designs, which add supplementary runs to the cube portion in particular directions in the experimental space, directions chosen by the experimenter perhaps after viewing the data from the cube portion or because of known restrictions in the omitted directions. The idea is to supplement the cube information by working in an interesting and favorable direction.
3. Small composite designs, in which the basic cube portion is fractionated to the point where some of the two-factor interactions are aliased with one another. These would be untangled using the

information obtained from the star portion (see, e.g., [1, Chapter 15]).

Special second-order designs, some of them rotatable, others not, also exist for situations where only three levels (coded $-1, 0, 1$) are possible (see [6], [1, Chapter 15], and **Box–Behnken Designs**). For examples of the use of central composite designs in split plot situations, see [7, p. 170].

Subsequent Analysis

If a second-order surface fits the data well, further analysis could take several forms such as plotting the surface represented by equation (2) if k were small ($k = 2$ or 3), plotting two-dimensional or three-dimensional sections if k were larger; performing canonical reduction, a technique that determines the principal features of the fitted surface for any value of k ; or performing ridge analysis (see **Ridge Analysis in Experimental Design**), which enables the following of a “best path” on the surface in any number of dimensions k , beginning at *any* selected point in the experimental space. In some cases, that selected point might simply be the coded design origin. Higher, lower, or intermediate local optima values of the response can be specified as desirable in the ridge analysis, and it is also possible to track the ridge path onto any designated linear restrictions (restrictive planes in the experimental space) that may be encountered by the initial best path. One such type of linear restriction occurs when the experiment is conducted in mixture ingredients adding to 1 (or any other level specified between 0 and 1) (see [1, Chapters 12 and 19] and **Mixture Experiments**).

It is also possible to fit many other types of special models if they make sense in the specific context. For example, a specific alternative mechanistic model (one that reflects the actual mechanism of the process) might be chosen by an experimenter who has the requisite applicable theoretical knowledge of the experimental mechanism under study (see [4, Chapter 12] and [8]).

Mixture Experiments

Introduction

A *mixture experiment* involves combining two or more components in various proportions or amounts and then measuring one or more responses for the resulting end products. Other factors that affect the response(s), such as process variables (PVs) and/or the total amount of the mixture, may also be studied in the experiment. A *mixture experiment design* specifies the combinations of mixture components and other experimental factors (if any) to be studied and the response(s) to be measured. *Mixture experiment data analyses* are then used to achieve the desired goals, which may include (a) understanding the effects of components and other factors on the response(s), (b) identifying components and other factors with significant and nonsignificant effects on the response(s), (c) developing models for predicting the response(s) as functions of the mixture components and any other factors, and (d) developing end products with optimal or desired values and uncertainties of the response(s).

Given a mixture experiment problem, a practitioner must consider the possible approaches for designing the experiment and analyzing the data, and then select the approach best suited to the problem. Eight possible approaches are (a) component proportions (CPs), (b) mathematically independent variables (MIVs), (c) slack variable (SV), (d) mixture amount (MA), (e) component amounts (CA), (f) mixture-process variable (MPV), (g) mixture of mixtures, (MoM) and (h) multifactor mixture (MFM). The article provides an overview of the mixture experiment designs, models, and data analyses appropriate for these approaches. For more discussion and examples of these approaches, see Piepel and Cornell [1]. Also, the books by Cornell [2] and Smith [3] are devoted to the design and data analysis of mixture experiments and are recommended for additional information. Piepel [4] summarizes 50 years of mixture experiment research from 1955 to 2004 along with an extensive bibliography.

Before designing a mixture experiment, a practitioner must choose the model form(s) likely to be adequate to achieve the objectives of the experiment, and then design the experiment to adequately support fitting the model form(s). Hence in

the subsequent section for each mixture experiment approach, appropriate models are discussed before experimental designs.

Component Proportions Approach

With the CP approach for mixture experiments, q mixture components and no other factors are studied. The experiment is designed and responses are modeled using the proportions of the mixture components x_i , which are subject to the constraints

$$0 \leq x_i \leq 1, i = 1, 2, \dots, q \text{ and } \sum_{i=1}^q x_i = 1 \quad (1)$$

The experimental region defined by these constraints is a $(q - 1)$ -dimensional simplex. Additional single-component constraints of the form

$$L_i \leq x_i \leq U_i, \quad i = 1, 2, \dots, q \quad (2)$$

and/or multiple-component constraints of the form

$$C_k \leq \sum_{i=1}^q A_{ki}x_i \leq D_k, \quad k = 1, 2, \dots, K \quad (3)$$

generally yield a $(q - 1)$ -dimensional polyhedral experimental region. The constraint in equation (1), that the mixture CPs must sum to one, means that the mixture CPs cannot be varied independently. This fact affects the choice of experimental designs and models for the CP approach (and some other approaches) to mixture experiments.

Scheffé Polynomial Models in Component Proportions

Polynomial models are often successful in modeling response surfaces based on Taylor series theory for approximating functions with polynomial expansions. However, the standard polynomial models must be modified to account for the mixture constraint $\sum_{i=1}^q x_i = 1$ in equation (1). Several commonly used Scheffé [5] polynomial models for CP mixture experiments are

Linear:

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i x_i \quad (4)$$

2 Mixture Experiments

Quadratic:

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} x_i x_j \quad (5)$$

Special cubic:

$$\begin{aligned} \eta(\mathbf{x}) = & \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} x_i x_j \\ & + \sum_{i=1}^{q-2} \sum_{j=i+1}^{q-1} \sum_{k=j+1}^q \beta_{ijk} x_i x_j x_k \end{aligned} \quad (6)$$

Full cubic:

$$\begin{aligned} \eta(\mathbf{x}) = & \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} x_i x_j \\ & + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \delta_{ij} x_i x_j (x_i - x_j) \\ & + \sum_{i=1}^{q-2} \sum_{j=i+1}^{q-1} \sum_{k=j+1}^q \beta_{ijk} x_i x_j x_k \end{aligned} \quad (7)$$

Full-quartic and special-quartic models are discussed by Smith [3, Section 3.4]. In all of these model forms, $\eta(\mathbf{x})$ is the expected value of the response at mixture $\mathbf{x} = (x_1, x_2, \dots, x_q)$. The $\sum_{i=1}^q \beta_i x_i$ model terms in equations (4–7) describe *linear blending* of the mixture components, while the remaining terms in equations (5–7) describe *nonlinear blending* of the mixture components in various degrees (i.e., quadratic, special cubic, and full cubic). The nonlinear blending terms are not referred to as *interaction terms*, because curvature and interaction effects of the mixture components are partially confounded as a result of the mixture constraint $\sum_{i=1}^q x_i = 1$. Methods for investigating curvature and interaction effects of mixture components are discussed by Cox [6] and Piepel *et al.* [7].

The coefficient β_i in equations (4–7) represents the expected value of the response at the pure mixture with $x_i = 1$ and $x_j = 0$ for $j \neq i$. Cornell [2, Sections 2.2 and 2.3] discusses the interpretations of other coefficients in mixture experiment models. However, all such interpretations are extrapolations when the experimental region is restricted by constraints of the form in equations (2) and/or (3).

Other Polynomial Models in Component Proportions

Cox [6] proposed using ordinary first- and second-degree polynomial models with the parameters constrained to estimate the main, curvature, and interactive effects of components in a way appropriate to mixture experiments. Cornell [2, Sections 6.7 and 6.8] and Smith and Beverly [8] discuss and illustrate the *Cox mixture polynomial models*. Piepel [9, 10] proposed *component-slope linear mixture (CSLM) models* with parameters representing the slopes of the **response surface** along the component effect directions. The advantage of the Cox and CSLM models over the Scheffé models is that their coefficients provide estimates of component effects. The disadvantage is that the models are overparameterized and involve constraints on the coefficients.

Scheffé quadratic models in equation (5) are adequate for many mixture experiment applications, but in practice only a few quadratic terms may be needed. *Partial quadratic mixture (PQM)* models of the form

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i x_i + \text{subset of} \left\{ \sum_{i=1}^q \beta_{ii} x_i^2 + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} x_i x_j \right\} \quad (8)$$

contain a subset of squared terms and/or cross-product terms. PQM models contain as a subset the set of reduced Scheffé quadratic models, and thus can more efficiently capture curvature as well as interactive effects of mixture components. See Piepel *et al.* [11] and Smith [3, Section 10.3] for discussion and illustrations of PQM models.

Nonpolynomial Models in Component Proportions

The mixture polynomial model forms previously introduced provide for adequately approximating many true response surfaces for mixture experiments, but there are situations when nonpolynomial model forms are more appropriate.

For CP mixture experiments where one or more components have additive effects, three *models homogeneous of degree one* proposed by Becker [12] are

appropriate

$$\begin{aligned} \text{H1: } \eta(\mathbf{x}) = & \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} \min(x_i, x_j) \\ & + \sum_{i=1}^{q-2} \sum_{j=i+1}^{q-1} \sum_{k=j+1}^q \beta_{ijk} \min(x_i, x_j, x_k) \quad (9) \end{aligned}$$

$$\begin{aligned} \text{H2: } \eta(\mathbf{x}) = & \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} \frac{x_i x_j}{x_i + x_j} \\ & + \sum_{i=1}^{q-2} \sum_{j=i+1}^{q-1} \sum_{k=j+1}^q \beta_{ijk} \frac{x_i x_j x_k}{x_i + x_j + x_k} \quad (10) \end{aligned}$$

$$\begin{aligned} \text{H3: } \eta(\mathbf{x}) = & \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} (x_i x_j)^{1/2} \\ & + \sum_{i=1}^{q-2} \sum_{j=i+1}^{q-1} \sum_{k=j+1}^q \beta_{ijk} (x_i x_j x_k)^{1/3} \quad (11) \end{aligned}$$

The cubic forms of these models are shown, but the quadratic forms (without the last group of terms in each model) are more frequently used in practice. For additional discussion of these models, see Cornell [2, Sections 6.3–6.5] and Snee [13].

For CP mixture experiments where the response variable increases rapidly as CPs approach zero, Scheffé linear and quadratic models with inverse terms

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^q \delta_i x_i^{-1} \quad (12)$$

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij} x_i x_j + \sum_{i=1}^q \delta_i x_i^{-1} \quad (13)$$

are appropriate. Inverse terms can be added to other mixture models such as in equations (6) and (7) if needed. It is only necessary to add inverse terms for those components needing them. For CPs that can equal zero, the corresponding x_i^{-1} in equations (12) and (13) are replaced with $(x_i + c_i)^{-1}$, where the c_i values are small positive constants. The forms of Scheffé models with inverse terms can also be modified for use when the response increases rapidly as constrained CPs approach their lower limits. See Cornell [2, Sections 6.1 and 6.2] for further discussion of these topics.

Log-contrast models were introduced by Aitchison and Bacon-Shone [14] for situations in which one or more mixture components are inert or have additive effects on the response. The linear and quadratic forms of the log-contrast models are given by

$$\eta(\mathbf{x}) = \gamma_0 + \sum_{i=1}^q \gamma_i \log x_i \quad (14)$$

$$\begin{aligned} \eta(\mathbf{x}) = & \gamma_0 + \sum_{i=1}^q \gamma_i \log x_i \\ & + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \gamma_{ij} (\log x_i - \log x_j)^2 \quad (15) \end{aligned}$$

which are overparameterized and thus subject to constraints on the parameters. For CPs that can equal zero, the corresponding $\log x_i$ in equations (14) and (15) are replaced with $\log(x_i + c_i)$. See Aitchison and Bacon-Shone [14] and Cornell [2, Sections 6.9 and 6.10] for additional discussion of the constraints on the parameters, interpretations of the parameters, and examples of these models.

Simplex Designs in Component Proportions

Four types of experimental design are commonly used to explore how responses depend on the proportions of mixture components over simplex experimental regions (either the whole simplex region as defined in equation (1) or a simplex-shaped subregion).

A $\{q, m\}$ simplex-lattice design consists of $\binom{q+m-1}{m} = (q+m-1)!/m!(q-1)!$ points with each component having $m+1$ equally spaced values of $0, 1/m, 2/m, \dots, 1$. For example, the $\{3, 2\}$ simplex-lattice design contains the six points $(x_1, x_2, x_3) = (1, 0, 0), (0, 1, 0), (0, 0, 1), (1/2, 1/2, 0), (1/2, 0, 1/2),$ and $(0, 1/2, 1/2)$. This design is pictured in Figure 1(a). As another example, the $\{4, 3\}$ simplex-lattice design contains 20 points including 4 permutations of $(1, 0, 0, 0)$, 12 permutations of $(1/3, 2/3, 0, 0)$, and 4 permutations of $(1/3, 1/3, 1/3, 0)$. A $\{q, m\}$ simplex-lattice design supports fitting a Scheffé polynomial model of degree m (see Cornell [2, Section 2.2]). For example, the $\{3, 3\}$ simplex-lattice design supports fitting the full-cubic model in equation (7).

A *simplex-centroid design* for q components contains $2^q - 1$ points, consisting of all permutations

Figure 1 Example designs for three mixture components with the CP approach: (a) {3, 2} simplex-lattice design, (b) simplex-centroid design, and (c) augmented simplex-centroid design

of $(1, 0, 0, \dots, 0)$, $(1/2, 1/2, 0, \dots, 0)$, $(1/3, 1/3, 1/3, 0, \dots, 0)$, ... as well as the centroid $(1/q, 1/q, 1/q, \dots, 1/q)$. Figure 1(b) illustrates this design for $q = 3$. The simplex-centroid design supports fitting the full Scheffé polynomial model in equation (4), as well as the Scheffé linear, quadratic, and special-cubic polynomial models in equations (5–7).

An *augmented simplex-centroid design* adds to the simplex-centroid design the q interior axial points of

the form $((q+1)/2q, 1/2q, 1/2q, \dots, 1/2q)$. This design for $q = 3$ is shown in Figure 1(c).

Snee and Marquardt [15] proposed a *simplex screening design* for q components that contains points along the component axes, including the q vertices of the form $(1, 0, 0, \dots, 0)$, the q axis endpoints of the form $(0, 1/q, \dots, 1/q)$, the q interior axial points of the form $((q+1)/2q, 1/2q, 1/2q, \dots, 1/2q)$, and the overall centroid $(1/q, 1/q, 1/q, \dots, 1/q)$. For $q = 3$, the simplex screening design is the same as the augmented simplex-centroid design shown in Figure 1(c).

When one or more mixture CPs are constrained by lower bounds $x_i \geq L_i$, the constrained experimental region is a simplex-shaped subregion of the whole simplex defined by equation (1). The simplex subregion can be transformed to the whole simplex by L -pseudocomponent transformations

$$x'_i = \frac{x_i - L_i}{1 - \sum_{j=1}^q L_j}, i = 1, 2, \dots, q \quad (16)$$

In such cases, any of the simplex designs described previously can be used. Designs expressed in proportions of the L -pseudocomponents can be transformed into designs expressed in proportions of the original components via

$$x_i = L_i + \left(1 - \sum_{j=1}^q L_j\right) x'_i \quad (17)$$

Constraints of the form $x_i \leq U_i$ can sometimes lead to a simplex-shaped subregion. Cornell [2, Section 4.6] discusses a U -pseudocomponent transformation that can be applied to adapt the simplex designs discussed previously to such situations.

Constrained Designs in Component Proportions

When there are single- and/or multiple-component constraints on the CPs, as in equations (2) and/or (3), the mixture experimental region is generally a convex polyhedron that can be irregular in shape. Designs for constrained CP mixture experiments are generally constructed by *optimal experimental design* methods. These methods involve selecting design points that satisfy the applicable constraints (possibly from a pregenerated candidate set) so as to optimize a selected design optimality criterion.

By analogy with **factorial** and **fractional factorial** designs for nonmixture variables on cuboidal experimental regions, candidate points often consist of all or some of the vertices and dimensional centroids (i.e., 1-D edge centroids, 2-D face centroids, ..., $(q - 2)$ -D face centroids, and the $(q - 1)$ -D overall centroid) of the constrained CP experimental region. Cornell [2, Section 4.9] discusses several algorithms for calculating all or a fraction of the vertices of a polyhedral experimental region defined by single-component constraints as in equation (2). Snee [16] and Piepel [17] discuss algorithms for calculating vertices and dimensional centroids for a constrained region defined by single- and/or multiple-component constraints of the forms (2) and/or (3). Mixtures in the interior of the constrained region, possibly obtained on a grid, are needed as candidate points for some design optimality criteria.

The most commonly used design optimality criteria include

D-optimality: Minimize $|(U'U)^{-1}|$, the generalized variance of the vector of estimated model coefficients.

G-optimality: Minimize $\max_{\mathbf{x} \in R} \{\mathbf{u}'(U'U)^{-1}\mathbf{u}\}$, the maximum standardized prediction variance over the constrained experimental region R .

I-optimality: Minimize $\text{avg}_{\mathbf{x} \in R} \{\mathbf{u}'(U'U)^{-1}\mathbf{u}\}$, the average standardized prediction variance over the constrained experimental region R .

In the preceding notation, $\mathbf{x}$ is a vector of predictor variables (e.g., mixture CPs), $\mathbf{X}$ is the experimental design matrix expressed in the predictor variables, and $\mathbf{u}$ and $\mathbf{U}$ are extensions of $\mathbf{x}$ and $\mathbf{X}$ in the form of the model for which an **optimal design** is desired. Note that *I-optimality* is sometimes referred to as *V-optimality* or *IV-optimality*. These optimality criteria (and others not listed here) are often called *alphabetic design optimality criteria* because letters of the alphabet are used to identify them.

Mathematically Independent Variables Approach

With the MIVs approach for mixture experiments, q mixture components and no other factors are studied. The MIVs approach can be extended to study nonmixture factors (e.g., total amount or PVs) in addition to the mixture components, but such extensions are

not discussed here. An MIVs experiment is designed and responses are modeled using $q - 1$ MIVs to which the q mixture CPs ($x_i, i = 1, 2, \dots, q$) have been transformed. The MIVs are denoted $z_i, i = 1, 2, \dots, q - 1$. Standard designs, models, and other response surface methodology for nonmixture experiments (see **Response Surface Methodology**) can be used on the basis of the $q - 1$ MIVs. For this reason, the MIV approach was widely used many years ago prior to the development of experimental design, modeling, and other methods specifically for mixture experiments. However, it is now recommended that the MIVs approach only be used if the transformation of q mixture CPs to $q - 1$ MIVs is natural or of long-standing practice. For example, in aluminum production the long-term practice has been to use the MIVs approach with bath ratio = NaF/AlF_3 in addition to other separate components such as Al_2O_3 , MgF_2 , and CaF_2 . Various forms of ratio transformations and other transformations to MIVs that are natural for a particular problem are possible. Cornell [2, Section 6.6] discusses the MIV approach using ratios of components. Cornell [2, Chapter 3] also discusses general methods for obtaining MIVs, although those methods typically do not yield transformations natural to any particular problem.

Slack Variable Approach

With the SV approach for mixture experiments, only mixture components and no other factors are studied. The experiment is designed and response(s) modeled using proportions of $q - 1$ of the q mixture components. For a given design in the $q - 1$ components, the proportion of the q th component (called the *slack variable*) is obtained by $x_q = 1 - x_1 - x_2 - \dots - x_{q-1}$ for each point in the design. In this sense the q th component “takes up the slack”. Standard designs, models, and other response surface methods (see **Response Surface Methodology**) are used with the SV approach. For example, the linear and quadratic models with the q th component as the SV are

Linear:

$$\eta(\mathbf{x}) = \alpha_0 + \sum_{i=1}^{q-1} \alpha_i x_i \quad (18)$$

Quadratic:

$$\eta(\mathbf{x}) = \alpha_0 + \sum_{i=1}^{q-1} \alpha_i x_i + \sum_{i=1}^{q-2} \sum_{j=i+1}^{q-1} \alpha_{ij} x_i x_j + \sum_{i=1}^{q-1} \alpha_{ii} x_i^2 \quad (19)$$

These models provide exactly the same fits as would the linear and quadratic Scheffé mixture models in equations (4) and (5). However, reductions of SV models can have different fits than reductions of Scheffé mixture models and can yield misleading conclusions.

The SV approach is often used when the component chosen as the SV (a) makes up most (e.g., $x_q \geq 0.80$) of the mixture, (b) has a negligible effect on the response(s), or (c) serves as a filler or diluent. In all of these cases applications or adaptations of the CP approach are appropriate, whereas the SV approach can result in misleading conclusions. In situation (a), a component that makes up the majority of a mixture often has large effects on the response variables. However, the effects of this component are confounded with the effects of other components in models such (18) or (19). Hence, the SV approach could lead to incorrect conclusions about the effects of other components as well as the SV component. It is better to use the CP approach in this situation. In situation (b), when a component has no effect on a response over the composition region of interest, the CP approach is appropriate, with the response depending on the proportions of the remaining components (i.e., $X_j = x_j / (1 - \sum_{k=1}^{q-1} x_k)$, with $j = 1, 2, \dots, q-1$). In situation (c), a filler or diluent component typically would not blend nonlinearly with the remaining components, but still may affect the response. In such cases, the CP approach using a model homogeneous of degree one (Becker H1, H2, and H3) or a log-contrast model should be used.

Mixture-Amount Approach

When a response variable is expected to depend on the total amount of the mixture as well as the proportions of the components, a MA approach should be used. An MA experiment is designed and the response(s) modeled in terms of the proportions (x_i) and total amount (A) of the mixture components. The

CPs are subject to the basic mixture constraints in equation (1), and possibly to single-component constraints in equation (2) and/or multicomponent constraints in equation (3). The total amount is typically restricted to fall within a specified range, often with two or three levels specified for study. Typically two levels of A are coded as $A' = -1$ and $+1$, while three levels are coded as $A' = -1, 0$, and $+1$.

Mixture-Amount Models

If the amount of a mixture affects a response but not the blending effects of the mixture components, then MA models have the general form

$$\eta(\mathbf{x}) = \{\text{Mixture model}\} + \{\text{Amount model}\} \quad (20)$$

The mixture model can take any permissible form in the CPs (e.g., the forms in equations (4–7)), while the amount model is typically a linear or quadratic polynomial in the amount A (or coded A'). Two example models of this type are

Linear–linear:

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i^0 x_i + \beta_0^1 A' \quad (21)$$

Quadratic–quadratic:

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i^0 x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij}^0 x_i x_j + \beta_0^1 A' + \beta_0^2 A'^2 \quad (22)$$

In equation (21), the mixture components blend linearly and the amount variable has a linear effect on the response. In equation (22), the mixture components blend quadratically and the amount variable has a quadratic effect on the response. In both equations, the component blending is not affected by the amount of the mixture (i.e., the components and amount do not interact).

If the amount of a mixture affects the component blending properties, then MA models have the general form

$$\eta(\mathbf{x}) = (\text{Mixture model})(\text{Amount model}) + \text{Mixture terms} + \text{Amount terms} \quad (23)$$

An example model of this form is

$$\eta(\mathbf{x}) = \left(\sum_{i=1}^q \beta_i x_i \right) (\alpha_0 + \alpha_1 A')$$

$$\begin{aligned}
& + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij}^0 x_i x_j + \beta_0^2 A'^2 \\
& = \sum_{i=1}^q \beta_i^0 x_i + \sum_{i=1}^q \beta_i^1 x_i A' \\
& + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij}^0 x_i x_j + \beta_0^2 A'^2 \quad (24)
\end{aligned}$$

where (a) the linear blending effects of the components are affected by the amount of the mixture, (b) the components have quadratic blending effects that are not affected by the amount of the mixture, and (c) the amount has the same quadratic effect on the response for all mixtures.

Mixture-Amount Designs

Complete MA designs can be formed by running a CP mixture experiment design at each of two or three (or more, if desired) levels of the amount variable. As an example, Figure 2 illustrates a constrained mixture design in three components performed at each of two levels of the amount variable. This design supports fitting a MA model of the form

$$\begin{aligned}
\eta(\mathbf{x}) = & \beta_1^0 x_1 + \beta_2^0 x_2 + \beta_3^0 x_3 + \beta_{12}^0 x_1 x_2 + \beta_{13}^0 x_1 x_3 \\
& + \beta_{23}^0 x_2 x_3 + \beta_{123}^0 x_1 x_2 x_3 + \beta_1^1 x_1 A' + \beta_2^1 x_2 A' \\
& + \beta_3^1 x_3 A' + \beta_{12}^1 x_1 x_2 A' + \beta_{13}^1 x_1 x_3 A' \\
& + \beta_{23}^1 x_2 x_3 A' + \beta_{123}^1 x_1 x_2 x_3 A' \quad (25)
\end{aligned}$$

With A coded to -1 and $+1$, the terms with 0 superscripts describe the component blending at

Figure 2 Example of a complete mixture-amount design for three constrained mixture components and two levels of total amount

the average of the two amounts (i.e., at zero-coded amount), while the terms with a 1 superscript describe the effect of the amount variable on the component blending properties relative to the average component blending properties.

Fractional MA designs can be formed with a fraction of a CP mixture design at one or more levels of the total amount variable. For example, the MA design with three mixture components and three levels of total amount shown in Figure 3 has a complete simplex-centroid design at $A' = -1$ and $+1$, but a vertex-only design at $A' = 0$. This design supports fitting the model

$$\begin{aligned}
\eta(\mathbf{x}) = & \beta_1^0 x_1 + \beta_2^0 x_2 + \beta_3^0 x_3 + \beta_{12}^0 x_1 x_2 + \beta_{13}^0 x_1 x_3 \\
& + \beta_{23}^0 x_2 x_3 + \beta_{123}^0 x_1 x_2 x_3 + \beta_1^1 x_1 A' + \beta_2^1 x_2 A' \\
& + \beta_3^1 x_3 A' + \beta_{12}^1 x_1 x_2 A' + \beta_{13}^1 x_1 x_3 A' \\
& + \beta_{23}^1 x_2 x_3 A' + \beta_{123}^1 x_1 x_2 x_3 A' + \beta_1^2 x_1 A'^2 \\
& + \beta_2^2 x_2 A'^2 + \beta_3^2 x_3 A'^2 \quad (26)
\end{aligned}$$

which assumes that the total amount has (a) linear effects on the linear and nonlinear blending properties of the mixture components and (b) a quadratic effect only on the linear blending properties of the mixture components.

Piepel *et al.* [18] discusses the special case of an MA experiment and models when the total amount takes a zero value in addition to nonzero values. These experiments are sometimes referred to as *mixture-amount-zero* (MAZ) experiments.

Component Amounts Approach

With the CA approach for mixture experiments, q mixture components and no other factors are studied. The CA approach can be extended to study nonmixture factors (e.g., total amount or PVs) in addition to the mixture components, but such extensions are not

Figure 3 Example of a fractional mixture-amount design with three mixture components and three levels of total amount

8 Mixture Experiments

discussed here. A CA experiment is designed and responses are modeled using amounts (e.g., masses or volumes) of the mixture components, denoted $a_i, i = 1, 2, \dots, q$. The amounts of mixture components are not subject to the constraints in equation (1) for mixture CPs. Hence, the experimental region of interest can be scaled to be cuboidal or spherical, enabling standard statistical designs such as *factorial*, *fractional factorial*, *Plackett–Burman*, **central composite**, *Box–Behnken*, and others to be used. Similarly, standard response surface models, such as

Linear:

$$\eta(\mathbf{x}) = \alpha_0 + \sum_{i=1}^q \alpha_i a_i \quad (27)$$

Linear plus interaction:

$$\eta(\mathbf{x}) = \alpha_0 + \sum_{i=1}^q \alpha_i a_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \alpha_{ij} a_i a_j \quad (28)$$

Quadratic:

$$\eta(\mathbf{x}) = \alpha_0 + \sum_{i=1}^q \alpha_i a_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \alpha_{ij} a_i a_j + \sum_{i=1}^q \alpha_{ii} a_i^2 \quad (29)$$

and other standard data analysis and graphics methods (see **Response Surface Methodology**) can be used with the CA approach.

When using the CA approach, information about effects of CPs (x_i) and effects of the total amount of the mixture ($\sum_{i=1}^q a_i = A$) are confounded because $a_i = x_i A, i = 1, 2, \dots, q$. If it is natural or desirable to separately understand the effects of the component (x_i) and total amount (A) variables on the response(s), then the MA approach (discussed previously) should be used. On the other hand, if it is natural or desirable, or to understand the effects of the CAs on the response(s), the CA approach is appropriate. Finally, if the total amount of the mixture turns out to have little or no effect on the response, the CA approach could complicate discovering it, so that the MA approach is preferred for such cases. See Piepel [19] for more discussion of the CA approach and how it compares to the MA approach.

Mixture-Process Variable Approach

With the MPV approach, the effects on a response variable of both mixture components and process

variables (a general term for “other factors”) are studied. A MPV experiment is usually designed and responses modeled in terms of the proportions of the mixture components and the levels of the PVs. The CPs are subject to the basic mixture constraints in equation (1), and possibly to single-component constraints in equation (2) and/or multicomponent constraints in equation (3). One or more PVs are typically restricted to fall within specified ranges. Often, two or three values of each PV are specified for study. Typically two levels of a PV would be coded as $z = -1$ and $+1$, while three levels would be coded as $z = -1, 0$, and $+1$.

Mixture-Process Variable Models

If the levels of PVs affect a response but not the blending effects of the mixture components, then MPV models have the general form

$$\eta(\mathbf{x}) = \{\text{Mixture model}\} + \{\text{PVs model}\} \quad (30)$$

The mixture model can take any permissible form in the CPs (e.g., the forms in equations (4–7)), while the PV model is typically a linear, linear plus interactions, or quadratic polynomial in the PVs. An example model of this type with two PVs (z_1 and z_2) is given by

$$\eta(\mathbf{x}) = \sum_{i=1}^q \beta_i^0 x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij}^0 x_i x_j + \beta_0^1 z_1 + \beta_0^2 z_2 + \beta_0^{12} z_1 z_2 \quad (31)$$

In this model, the mixture components blend quadratically and the PVs have linear and interactive effects. However, the component blending is not affected by the PVs (i.e., the components and PVs do not interact).

If the levels of PVs affect the component blending properties (which happens frequently in practice), then MPV models have the general form

$$\eta(\mathbf{x}) = (\text{Mixture model})(\text{PVs model}) + \text{Mixture terms} + \text{PVs terms} \quad (32)$$

An example model of this form is

$$\eta(\mathbf{x}) = \left(\sum_{i=1}^q \beta_i x_i \right) (\alpha_0 + \alpha_1 z_1 + \alpha_2 z_2)$$

$$\begin{aligned}
& + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij}^0 x_i x_j + \beta_0^1 z_1^2 \\
& = \sum_{i=1}^q \beta_i^0 x_i + \sum_{i=1}^{q-1} \sum_{j=i+1}^q \beta_{ij}^0 x_i x_j + \sum_{i=1}^q \beta_i^1 x_i z_1 \\
& \quad + \sum_{i=1}^q \beta_i^2 x_i z_2 + \beta_0^{11} z_1^2 \quad (33)
\end{aligned}$$

where (a) the linear blending properties of the components are affected by linear effects of the PVs, (b) the components have quadratic blending properties that are not affected by the PVs, and (c) one PV (z_1) has a quadratic effect on the response that is the same for all mixtures.

Mixture-Process Variable Designs

A *complete MPV design* is formed by running the same CP mixture experiment design at each point in a PV design (or vice versa). A *fractional MPV design* results from running different mixture designs at each PV design point (or vice versa). As an example, Figure 4 illustrates a simplex-centroid mixture design in three components performed at each of the four combinations in a 2^2 design for two PVs. This 28-point complete MPV design supports exactly fitting a 28-term model of the form

$$\eta(\mathbf{x}) = \beta_1^0 x_1 + \beta_2^0 x_2 + \beta_3^0 x_3 + \beta_{12}^0 x_1 x_2 + \beta_{13}^0 x_1 x_3$$

Figure 4 Example of a complete mixture-process variable design with a simplex-centroid mixture design in three components at each of the four combinations of a 2^2 design for two process variables

$$\begin{aligned}
& + \beta_{23}^0 x_2 x_3 + \beta_{123}^0 x_1 x_2 x_3 + (\beta_1^1 x_1 + \beta_2^1 x_2 \\
& + \beta_3^1 x_3 + \beta_{12}^1 x_1 x_2 + \beta_{13}^1 x_1 x_3 + \beta_{23}^1 x_2 x_3 \\
& + \beta_{123}^1 x_1 x_2 x_3) z_1 + (\beta_1^2 x_1 + \beta_2^2 x_2 + \beta_3^2 x_3 \\
& + \beta_{12}^2 x_1 x_2 + \beta_{13}^2 x_1 x_3 + \beta_{23}^2 x_2 x_3 + \beta_{123}^2 x_1 x_2 x_3) z_2 \\
& + (\beta_1^{12} x_1 + \beta_2^{12} x_2 + \beta_3^{12} x_3 + \beta_{12}^{12} x_1 x_2 \\
& + \beta_{13}^{12} x_1 x_3 + \beta_{23}^{12} x_2 x_3 + \beta_{123}^{12} x_1 x_2 x_3) z_1 z_2 \quad (34)
\end{aligned}$$

With z_1 and z_2 coded to -1 and $+1$ the terms with 0 superscripts describe the component blending at the average levels of the PVs (i.e., zero-coded values). Terms with a 1 or a 2 superscript describe the effects of the first or second PV on the component blending properties relative to the average component blending properties. The terms with a 12 superscript describe the interactive effects of the two PVs on the component blending properties relative to the average component blending properties.

Sometimes MPV designs are run as **split-plot** experiments when the mixture blends or the PVs are hard to change. When the mixture components are hard to change, all points in a PV design are run together for each point in a mixture design. When the PVs are hard to change, all points in a mixture design are run together for each point in a PV design. MPV designs run as split-plot experiments require special data analysis methods to account for the restriction on **randomization** of the design points. See Cornell [2, Sections 7.3 and 7.4] and Kowalski *et al.* [20] for additional discussion of the design and analysis of MPV split-plot experiments.

Mixture-of-Mixtures Approach

With the MoM approach, the end product is a mixture of main components (sometimes called *major components*), which are themselves mixtures of sub-components (sometimes called *minor components*). For example, an ink-jet printer image is a mixture of three to six colors of inks, with each ink a mixture of chemicals. In some cases the main components represent categories of components, and the sub-components are kinds of ingredients in each category. Such cases are referred to as *categorized component* (CC) mixture experiments.

There are two types of MoM/CC experiments. In one type (type A), the proportions of the main

Figure 5 The $\{2, 2; 2, 2\}$ double-lattice design for a mixture-of-mixtures experiment

components have fixed values and only the proportions of the subcomponents are varied. In this type of MoM/CC experiment, only the blending among subcomponents is studied. In the other type (type B) of MoM/CC experiments, the proportions of the main components and the subcomponents are varied. In this type of experiment, blending among main components and among subcomponents is studied. Models and designs for both types of MoM/CC experiments are discussed by Cornell [2, Section 4.13]. In an example discussed by Cornell [2, Section 4.13.2] the main components are two types of resins, with two subcomponents (x_1 and x_2 for the first type, x_3 and x_4 for the second type). The $\{2, 2; 2, 2\}$ double-lattice design used in this example is shown in Figure 5. The corresponding double-Scheffé (quadratic–quadratic) model is

$$\begin{aligned} \eta(\mathbf{x}) = & \gamma_{13}x_1x_3 + \gamma_{14}x_1x_4 + \gamma_{23}x_2x_3 + \gamma_{24}x_2x_4 \\ & + \gamma_{123}x_1x_2x_3 + \gamma_{124}x_1x_2x_4 + \gamma_{134}x_1x_3x_4 \\ & + \gamma_{234}x_2x_3x_4 + \gamma_{1234}x_1x_2x_3x_4 \end{aligned} \quad (35)$$

See Cornell [2, Section 4.13.2] for further discussion of this example. Piepel [21] discusses methods for developing and reducing models for type A MoM experiments with a pharmaceutical tablet formulation example.

Multifactor Mixture Approach

In a *MFM* experiment, mixture experiments are performed for each of two or more independent mixture factors in an experiment. If there are

n mixture factors each having $q_k (k = 1, 2, \dots, n)$ components, then the experimental region is $(\sum_{k=1}^n q_k - n)$ dimensional.

Nigam [22] discusses an MFM example in which the goal is to maximize recombination frequency of a mixed bacterial culture (male and female) when irradiated with short exposures of mixtures of mutagens (x-rays and γ -rays). In this example there are two mixture factors, bacterial strains and mutagens, with each having two components. Note that the two mixture factors are independent and are not themselves major components of a mixture, which differentiates MFM experiments from MoM/CC experiments. Nigam [22] discusses designs and models for MFM experiments.

Optimal Experimental Design

Optimal experimental design methods were discussed previously for the CP approach, but can be used with most of the approaches when needed. Exceptions are the MoM and MFM approaches, where the methods are applicable but not currently implemented in available software. Two common situations when optimal experimental design is needed are (a) the experimental region is irregular in shape because of linear constraints on the variables, and (b) the standard designs for a given approach contain too few or too many design points compared to the desired number.

For optimal experimental design methods that require a set of candidate points, the algorithms of Piepel [16] provide for generating the vertices and various dimensional centroids of any polyhedral region defined by linear inequality constraints on mixture variables, nonmixture variables, or both. Those algorithms only allow for at most one equality (mixture) constraint and hence are applicable to all but the MoM and MFM approaches. Even for those approaches candidate points can be generated separately and combined. However, the optimal design algorithms and software for candidate and candidate-free methods would have to be modified to account for more than one equality (mixture) constraint.

Optimal design methods are very useful for generating nonstandard designs, but there are three cautions to keep in mind. First, optimal designs (especially if constructed using vertices and dimensional centroids as candidate points) often have all (or nearly

all) design points on or near the boundary of the constrained experimental region. It may be desirable to have a substantial fraction of the design points in the interior of the experimental region. *Space-filling designs* (sometimes referred to as **uniform designs**) are one alternative to obtain a more even coverage of the interior as well as the exterior of a constrained experimental region. Piepel [4, Table 2] lists several publications that discuss uniform designs for CP mixture experiments. Other alternatives are the *central composite analog designs* (CCADs) and *layered designs* (LDs) proposed by Piepel *et al.* [23] to assure having design points on different layers of the constrained experimental region. **Ordinary central composite designs** can be used with the MIV, SV, CA approaches, and the PV portion of an MPV experiment. CCADs can be applied with the CP approach or the mixture portion of the MA or MPV approaches. LDs can be applied with any of the mixture approaches.

The second caution is that optimal designs are constructed for a specific model form, and may not be optimal or even good for other model forms. This tends to be the case when a design is optimized for a simpler (smaller) model but a larger model is more appropriate. However, designs optimized for a larger model often tend to be good for reduced forms of that model. Hence, construction of optimal designs for the largest model form that may be needed is generally recommended.

The third caution is that the number of design points must be specified in the optimal design approach. Practitioners should investigate optimal designs with fewer and more points than the desired number and assess the sensitivity of design properties to the number of design points.

Assessing and Comparing Designs

Piepel [4, Section 5] summarizes several analytical and graphical methods for assessing and comparing mixture designs. These include design efficiency measures, collinearity and leverage diagnostics, variance and **bias** dispersion graphs, fraction of design space plots, and other kinds of prediction variance plots. Many of these methods are applicable or can be adapted regardless of the mixture experiment approach used. For discussion of these methods, see **Assessment of Experimental Designs** and the associated references in [4].

Data Analyses for Mixture Experiments

The data analysis process for a mixture experiment usually begins by fitting and assessing models (corresponding to the selected approach) until a model is obtained that does not substantially underfit or overfit the data. Traditional regression methods for assessing model **lack of fit** are applicable to all of the mixture experiment approaches. However, appropriate formulas must be used to calculate entries of the analysis of variance table and related statistics (e.g., R^2) associated with models using the CP, MA, MPV, MoM, and MFM approaches (see Cornell [2, Section 5.2]).

After an adequately fitting model is obtained, it can be used to achieve the desired goals of the experiment. If the goal is to identify important (and unimportant) mixture components in the CP approach, numeric estimates of component effects can be calculated or displayed graphically using response trace plots (see Cornell [2, Section 5.9] and Smith [3, Section 11]). These methods can be adapted for the MA and MPV approaches. If the goal is to select settings of the mixture and/or nonmixture variables to optimize one response variable, standard optimization methods can be used for any of the approaches. If there are two or more response variables, multiresponse optimization methods can be applied for any of the approaches. Cornell [2, Sections 8.13 and 8.14] and Smith [3, Section 12.2] discuss these methods for the CP approach.

Piepel [4, Section 7] lists and provides references for many other data analysis methods applicable for the CP, MA, and MPV approaches. Several of these are also discussed throughout the book by Cornell [2]. Standard data analysis methods from *response surface methodology* are applicable to the MIV, CA, and SV approaches, but can result in misleading conclusions for the SV approach as noted previously.

Choosing a Mixture Experiment Approach

Choosing a mixture experiment approach depends primarily on the types of variables whose effects on the response variables are to be studied in the experiment. If only mixture variables (components) affect the response(s) and are to be studied, then the CP, MIV, and SV approaches are possible. However, the CP approach is recommended in general because the experiment is designed, the data are

analyzed, and conclusions are made directly in terms of the proportions of the mixture variables. The MIV approach can be appropriate if the MIVs are the natural or long-standing variables of interest for a particular problem. The SV approach is not recommended because of the potential for making wrong interpretations and conclusions.

If the total amount of the mixture as well as the CPs affect the response(s), then the MA and CA approaches are possible. The MA approach is recommended when the effects of the components and the effect of the total amount of the mixture are to be studied, understood, and optimized separately. The CA approach is appropriate when the effects of amounts of the individual components are to be studied, rather than effects of the component proportions and total amount.

The MPV approach should be used when the effects on the response(s) of mixture components and PVs are to be studied simultaneously. While it is possible to use the MIV and SV approaches in a MPV situation, doing so is not recommended because these approaches do not directly study all of the mixture components and PVs.

Finally, the MoM and MFM approaches are used in special cases that involve more than one mixture. The MoM approach is appropriate when the components of a primary mixture are in turn mixtures of subcomponents, hence the terminology of *mixtures-of-mixtures*. The MFM approach is appropriate when there are two or more independent factors to be studied in an experiment, and the factors are mixtures of different sets of components.

Response Surface Methodology

Introduction

Response surface methodology (RSM) is a strategy for exploring the relationship between controllable factors and important response variables. RSM makes extensive use of statistically designed experiments and regression models (*see* **Least-Squares Estimation**). A key element to RSM is the notion of sequential learning (*see* **Sequential Experimentation**): where initial experiments help focus attention on the most important factors, subsequent steps help to bring these factors to settings that achieve good results, and finally efficient statistical modeling techniques are used to estimate how these factors affect the response variables of greatest importance.

RSM was first introduced in a pathbreaking paper by Box and Wilson [1]. That article introduced the ideas of sequential experiments, the central composite design (*see* **Central Composite Designs**) and the use of **sequential experimentation** to find optimal operating conditions for a chemical process. Box continued to develop these ideas in two further articles [2, 3], developed new classes of designs [4, 5] and introduced the concepts of rotatability ([6], **Rotatable Designs and Rotatability**) and minimum **mean squared error** designs [7].

Applications

RSM is one of the most influential and widespread scientific methods proposed in the twentieth century. It has been used in a wide variety of fields such as chemistry, engineering, materials science, and biology, among others. We illustrate RSM with a biotechnology study by Kawaguti, Manrich and Sato [8]. That study aims at finding conditions for achieving a high rate of activity of glucosyltransferase, an enzyme that has important uses in the food industry. The enzyme is produced by bacteria in a culture medium. Various nutrients can be added to the medium and some of these may promote enzyme activity. The experiments described here studied three such nutrients: bacteriological peptone (BP), yeast extract and sugar cane molasses (SCM). The first two factors

were included as sources of nitrogen and the third as a source of carbon.

The Sequential Strategy

In this section we provide an overview of the strategic approach that guides RSM. Most applications begin with a rather large number of potential experimental factors and one or more important process outcomes. The study by Kawaguti, Manrich and Sato focused on just three factors [8], but the original article actually mentions quite a few additional factors, including the basal medium used for the culture, amounts of sucrose, beef and agar that were added to the medium, incubation conditions of the cultures, the speed and duration in which culture flasks were shaken, and the time allotted for fermentation. The ultimate goal of this investigation was to discover how enzyme activity depends on the factors under study and to find good operating conditions.

The following steps are typical in RSM studies:

- screening – identifying which of the factors are really critical for performance;
- effect **estimation** – estimating the effect of each of the important factors;
- steepest ascent – following an estimated direction of steepest ascent to achieve better results;
- response modeling – fitting a more complex regression model that includes nonlinear effects of the factors;
- optimization – using the fitted surface to estimate optimal operating conditions.

The screening step is quite intuitive. Suppose the screening step identifies two key factors and we proceed with these factors to the next steps. An effective analogy to understand the remaining journey is to think of climbing to the top of a mountain. Imagine a contour map in which our two factors form the north–south and east–west axes and the contour lines map regions of high and low response. We cannot see the map. Our only information comes from running experiments that expose the likely height at particular factor settings. Early in the RSM program we are often near the base of the mountain. Our experiments for estimating effects will pick up the direction of the slope that leads us uphill. Experiments along the line of steepest ascent follow this route up until we reach a crest. Then, further

experiments may be used to identify a new direction of steepest ascent. When we approach the peak of the mountain, we conduct more extensive experiments that enable us to model the topography of the contour map. The results of those experiments can be used to help identify the location of the peak. When more than two factors pass the screening phase, the visual analogy of the mountain climber is less immediate, but the same ideas can be applied to explore and map the surface, assess factor effects and discover optimal factor settings.

Many decisions confront the RSM team at each stage of the journey:

1. Should factors be dropped?
2. Should new factors be added?
3. Should the range of one of the factors be moved?
4. Should the range be made narrower? Wider?
5. Should points be added to a given design to accommodate more complex models?

No two experimental teams will make the same decisions. Yet the RSM strategy offers great flexibility, so that there are many routes to success.

The approach described above relies heavily on the ability to “learn as you go”. Results from the screening experiment will be valuable in deciding whether to drop a factor or to add a new factor. Identifying trends that point to better performance will often lead to changing the range of a factor in subsequent steps. Sequential experimentation thus plays a key role in RSM. And it is not surprising that industrial problems led to the birth of RSM; unlike the agricultural experiments that preceded them, industrial experiments could provide the rapid feedback needed for sequential work.

Screening Experiments

The initial phase of many RSM investigations is to identify the most important factors from what may be a long list. The best designs at this stage are ones that enable the team to study a large number of factors relative to the number of experimental runs that are made. Thus it is common to limit the experimental factors to just two levels and to use designs like small 2^{k-p} fractional factorials (see **Fractional Factorial Designs**); and Plackett and Burman designs [9] (see **Plackett–Burman Designs**). See also **Screening Designs**; **Main Effect Designs**. When there are many

candidate factors, one might even want to use a *supersaturated design* (see **Supersaturated Designs**), in which the number of factors is greater than or equal to the **sample size**. Interested readers can consult those entries for details.

Effect Estimation

At this stage, experimental results are used to estimate how changing each factor affects the response variables. Often this stage concentrates on main effects of the factors (see **Main Effects**). Sometimes there are *interactions* (see **Interactions**) between factors; i.e., the effect of a factor on the response is not always the same, but in fact depends on how some other factor has been set. When enough data are available, interactions can be estimated alongside main effects. Again two-level experimental designs are the ones most commonly used. Center points (see **Center Points**), in which all factors are set to an intermediate level, may also be added to the design. Center points allow the RSM team to check for the possibility that a full second-order regression model is needed. Usually more than one **center point** is included, which also permits a “model free” estimate of the experimental variability. Sometimes the effects are estimated from the screening experiment data.

Table 1 shows 11 experimental runs made by [8] in their first experiment, which correspond to a 2^3 design with three center points. In fitting regression models to data from these experiments, it is common to use “coded” versions of the factors in which the high-level is coded to 1 and the low level to -1 . As in this experiment, the intermediate level will typically be exactly between the high and low levels, and so will be coded to zero.

With the 2^3 design, it is possible to estimate all the main effects and interactions of the three factors. Analysis of these data reveals several important features:

1. Most settings give very low enzyme activity, but two runs generated much higher activity.
2. There is a strong **main effect** for SCM.
3. There is a strong main effect for yeast extract Prodex (YEP).
4. There is a very strong interaction effect of SCM and YEP.
5. Effects for BP are weak.

Table 1 Data from the first RSM experiment performed by Kawaguti *et al.* [8]. Coded values for the factors are given in parentheses. Actual levels of all factors are in g/L

Sugar cane molasses (X_1)	Bacteriological peptone (X_2)	Yeast extract Prodex (X_3)	Enzyme activity (Y) (in U/mL)

219.64 (1)	18.10 (−1)	37.14 (−1)	0.13
130.36 (−1)	41.90 (1)	37.14 (−1)	5.97
219.64 (1)	41.90 (1)	37.14 (−1)	0.20
130.36 (−1)	18.10 (−1)	72.86 (1)	0.63
219.64 (1)	18.10 (−1)	72.86 (1)	0.28
130.36 (−1)	41.90 (1)	72.86 (1)	0.32
219.64 (1)	41.90 (1)	72.86 (1)	2.12
175 (0)	30 (0)	55 (0)	0.42
175 (0)	30 (0)	55 (0)	0.47
175 (0)	30 (0)	55 (0)	0.48

6. The results at the center points are much lower than the average result at the **factorial** points, suggesting that there may be value in fitting a full second-order regression model.

Figure 1 shows a contour plot of the estimated response, as a function of SCM and YEP, when BP is at its intermediate level. The most important conclusion above is the first, which suggests that the experimental regime for these first runs was most likely too wide, placing most runs in regions of the factor space where there was little enzyme activity. The two runs with high activity suggest that there may be great advantage in repeating the experiment, but modifying the settings for the factors.

Steepest Ascent

Let $X_1, \dots, X_k$ denote the k factors (in coded units) in an initial experiment to estimate factor effects. Often the analysis shows that a first-order regression model gives a good fit to the response Y :

$$\hat{Y} = b_0 + b_1X_1 + b_2X_2 + \dots + b_kX_k \quad (1)$$

Here the b_j are the coefficients estimated by fitting a regression model to the data and $\hat{Y}$ is the estimated value of the response.

A first-order regression model is appropriate when the response is affected in a simple and linear fashion by the factors. If, for example, we were to start from the center point of the design and “move away” in a fixed direction, the response

Figure 1 Contour plot of the estimated enzyme activity based on the 11 runs in Table 1. The factor SCM is on the horizontal axis and the factor YEP is on the vertical axis; both are in coded units. The third factor, BP, is set to its intermediate level, 30

would change proportionally to our distance from the center point. The idea of steepest ascent is simply to move in the direction that gives the largest slope in the desired direction (positive if we want to maximize the response, negative if we want to minimize the response). It is easy to find this direction by differentiating the estimated regression equation. The direction of steepest ascent is proportional to the vector of slope coefficients: $(b_1, b_2, \dots, b_k)$. For

150 (0)	35 (1.68)	30 (0)	7.47
150 (0)	20 (0)	10 (−1.68)	8.47
150 (0)	20 (0)	50 (1.68)	7.06
150 (0)	20 (0)	30 (0)	8.43
150 (0)	20 (0)	30 (0)	8.23
150 (0)	20 (0)	30 (0)	7.83

example, suppose the estimated equation were $\hat{Y} = 21 + 4X_1 + 7X_2 - 5X_3$. The direction of steepest ascent would be (4, 7, −5), meaning that for each increase of X_1 by 4 coded units, we should increase X_2 by 7 coded units and we should decrease X_3 by 5 coded units. If we wanted to minimize the response, we could proceed in the direction of steepest descent: for each decrease of X_1 by 4 coded units, we should decrease X_2 by 7 coded units and we should increase X_3 by 5 coded units. Note that the two directions are exactly opposite to one another.

Applying the method of steepest ascent will typically lead to “moving” the factor ranges away from those used in the initial experiment to settings that give better results.

For the data we have presented on enzyme activity, there was a strong interaction. Hence a first-order regression model – and steepest ascent – will not be appropriate.

Response Modeling and Optimization

If the RSM team is experimenting in the region of a maximum or a minimum, a first-order regression model will not fit the data well. Instead, a second-order regression model will be needed. The most popular experimental design for fitting a second-order model is the central composite design proposed by

Box and Wilson [1] (see **Central Composite Designs**). This design includes points from a two-level factorial design, points along the “factor axes” and center points. Other popular designs are those developed by Box and Behnken [4, 5] (see **Box–Behnken Designs**).

The biotechnology study used a central composite design at the second stage; the results are listed in Table 2. Dramatic improvement is evident relative to the first phase of experimentation, as all settings now generate strong enzyme activity. The fitted second-order regression model, with all factors in coded form, is

$$\begin{aligned}\hat{Y} = & 8.13 + 0.56SCM - 0.04BP - 0.33YEP \\ & - 0.64SCM^2 - 0.19BP^2 - 0.01YEP^2 \\ & - 0.27SCM \times BP - 0.30SCM \times YEP \\ & - 0.63BP \times YEP\end{aligned}\quad (2)$$

There is a strong quadratic effect of SCM, a linear effect of YEP and strong interactions among all the factors.

There are a number of tools, both analytical and graphical, that can help us to better understand the nature of this fitted model. On the analytical side, second-order surfaces can be characterized algebraically. All have a “stationary point,” found by computing the partial derivatives of the surface with

respect to each factor, in turn, equating the partial derivatives to zero, and solving for the factor levels that simultaneously solve these equations. If the surface has an absolute minimum or maximum, it will occur at the stationary point. The second-order terms (pure quadratics and interactions) can be set up in a matrix. The eigenvalues and eigenvectors of the matrix show how the estimated response changes as the factors are moved away from the stationary point. The eigenvectors define new “axes” in the factor space. Moving along an axis with a positive eigenvalue, the value of the surface increases quadratically; the larger the eigenvalue, the steeper the increase. Similarly, if the eigenvalue is negative, the value of the surface decreases quadratically. The surface has a maximum (minimum) if all the eigenvalues are negative (positive).

Sometimes an eigenvalue is close to zero. This means that the surface has a “ridge”; i.e., a direction in the factor space along which the response stays nearly constant. Ridges can be of great value in a response surface study. They point to a large area in the factor space where similar results can be achieved. For example, suppose we want to maximize **process yield** and have run an experiment in which one of the factors is the viscosity of a blend produced at an intermediate stage of the production process, and another is the baking temperature at the next stage. The fitted regression model has an absolute maximum but also has a ridge corresponding to combinations of viscosity and temperature. Then any settings of viscosity and temperature along the ridge give only slightly lower estimated yield than is found at their optimal settings. This means that we can measure the viscosity after the intermediate stage and, if it is not at its optimal level, we can adjust the temperature to compensate, still achieving near optimal yield.

In the enzyme activity study, the stationary point of the fitted surface for the second experiment is at $SCM = 0.57$, $BP = -0.80$ and $YEP = 0.17$. The eigenvalues of the surface are 0.23, -0.31 and -0.76 . This means that there are two “directions” away from the stationary point in which the estimated surface decreases, i.e. in which the equation from the experimental data predicts lower enzyme activity. However, there is one direction in which there is an estimated increase in activity. That direction is given by the eigenvector that matches the positive eigenvalue, and has coefficients very close to 0, -0.6 and 0.8 for SCM , BP and YEP , respectively. Thus

the fitted surface predicts that we can achieve higher activity by keeping SCM at its stationary value of 0.57 , while modifying the (coded) BP and YEP in a ratio of -3 to 4 units. Had *all* the eigenvalues been negative, the fitted surface would have an absolute maximum at the stationary point.

A full discussion of the analytical properties of second-order response surface models is beyond the scope of this article; for details, see one of the books mentioned earlier. Ridge analysis is another useful method for exploring a second-order regression model; see **Ridge Analysis in Experimental Design**.

Graphic tools for visualizing response surfaces are available in many software packages. We used the contour plotting options in JMP® to explore the surface for the second phase of the enzyme activity experiment. The quadratic dependence on SCM is such that any value between 0 and 1 in coded units (150 – 180 in actual units) gives very good responses. The dependence on BP and YEP is related to the strong interaction between them. Figure 2 shows a contour plot of the estimated enzyme activity, as a function of YEP and BP , when SCM is set at 165 . The best estimated response values occur when YEP is set near 18 (-1 in coded units) and BP near 30 (1 in coded units). The increase in estimated activity as YEP and BP are moved from the center of Figure 2 to the lower right corner exactly matches the trend found by analyzing the eigenvalues of the fitted surface.

Figure 2 shows that the estimated response is very sensitive to the choice of YEP when BP is near 30 , but is rather insensitive to the choice of YEP when BP is set to lower levels (20 or less), with only a modest reduction in estimated enzyme activity. Sometimes this added “robustness” to inexact factor settings is sufficiently important that it may be worthwhile to move operating conditions away from the levels that appear to be “optimal” from the estimated regression.

Discussion

RSM is a strategy for sequentially exploring the relationship between a set of prospective process factors and one or more response variables. It has enjoyed great success in a wide variety of scientific and technological domains.

There are many statistical tools that have been developed under the umbrella of RSM. These include

Figure 2 Contour plot of the estimated enzyme activity based on the 17 runs in Table 2. The factor BP is on the horizontal axis and the factor YEP is on the vertical axis; both are in coded units. The third factor, SCM, is set to 165, which gives high estimated activity for all values of the other factors

the central composite and **Box–Behnken** designs for second-order regression models, rotatability in design, fitting and exploring second-order (and higher-order) regression models and ridge analysis. Some researchers will write that they are carrying out a response surface study whenever they use any one of these tools. However, that ignores the very central role of sequential experimentation in RSM. The spirit of RSM is very much in the iterative interplay between the experimental team and the data found at each stage of exploration. As more experiments are run, the RSM team gets a better picture of which factors are important, of the useful ranges of those factors and of how the response depends on the factors in those ranges. In turn, that allows the team to design more penetrating and informative experiments, providing data that further expose the relationships between the factors and the responses. This iterative process continues until the experimenters have achieved the understanding needed to make improvements and achieve goals.

Further Reading

This short article has briefly described the basic concepts and methods of response surface methodology. Readers interested in more detail can find thorough accounts of RSM in the books by Box and Draper [10], Myers and Montgomery [11] and Khuri and Cornell [12]. RSM was the featured topic in the January 1999 issue of the *Journal of Quality Technology*. That issue includes an excellent review by Myers [13], summarizing recent research and setting out future directions, articles by Box and Liu [14] and Box [15] that discuss the role of RSM in the scientific learning process, and thoughtful discussions by several leading statisticians. Finally, readers can find an up-to-date review of RSM research in Myers *et al.* [16].

Rotatable Designs and Rotatability

Coding the Experimental Conditions

Two levels of a predictor variable can always be coded to -1 and $+1$. For example, if two temperatures $T = 125$ and 175°C were to be used, the **coding** $(T - 150)/25$ would achieve the coded levels. Note that the coded level zero (here 150°C) would be the center of the range selected. Typically the center of the entire design would represent the *current best set of conditions within the experimental region* and the experiment would attempt to find the best manner of moving outwards to improve the response. With two variables, say temperature and pressure, the coded levels of a 2^2 design would be $(x_1, x_2) = (-1, -1), (-1, 1), (1, -1),$ and $(1, 1)$ and this design would provide enough information to fit a first order model (a plane) in the two-dimensional experimental space. Adding one or more **center points** at $(0, 0)$ would enable us to create a general “**lack of fit** test for planarity”.

For a second-order design, additional experimental points would be needed to provide at least three levels for each variable x_i . These points would also be coded using the same coding formulas. In what follows, we assume the coding has taken place.

The Variance Function of an Experimental Design in General

Suppose, for the moment, that an experimental design with n runs has been performed and the data are available. We then fit a selected model, for example, a polynomial of first or second order, and then interpret the resulting fitted surface. In general regression notation we fit a model of the form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (1)$$

where the n rows of $\mathbf{X}$ all have the same general form but enough distinct values to permit **estimation** of the model under consideration. For a first-order model, the form of the u th row of $\mathbf{X}$ would be $(1, x_{1u}, x_{2u}, \dots, x_{ku})$ and, for a second-order model $(1, x_{1u}, x_{2u}, \dots, x_{ku}, x_{1u}^2, x_{2u}^2, \dots, x_{ku}^2, x_{1u}x_{2u}, x_{1u}x_{3u}, \dots, x_{k-1,u}x_{ku}), u = 1, 2, \dots, n$. The column vector

$\boldsymbol{\beta}$, written out here as a row to save space, is correspondingly labeled $(\beta_0, \beta_1, \beta_2, \dots, \beta_k)$ for first order or $(\beta_0, \beta_1, \beta_2, \dots, \beta_k, \beta_{11}, \beta_{22}, \dots, \beta_{kk}, \beta_{12}, \beta_{13}, \dots, \beta_{k-1,k})$ for second order. Let $r^2 = \mathbf{x}'\mathbf{x} = x_1^2 + x_2^2 + \dots + x_k^2$ where $\mathbf{x} = (x_1, x_2, \dots, x_k)'$ is a general point in the space of the predictor variables. Thus, r is the distance of a general point $\mathbf{x}$ from the coded origin $(0, 0, \dots, 0)$ of the design space. It can be shown that, at any such specified point, the variance of the fitted response is given by

$$V(\hat{y}) = \mathbf{z}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{z}\sigma^2 \quad (2)$$

where $\mathbf{z} = (1, x_1, x_2, \dots, x_k)'$ for a first-order model and $\mathbf{z} = (1, x_1, x_2, \dots, x_k, x_1^2, x_2^2, \dots, x_k^2, x_1x_2, x_1x_3, \dots, x_{k-1}x_k)'$ for a second-order model where σ^2 is $V(y)$, the variance of a single original observation y . (The σ^2 would usually be estimated from the residual mean square in an analysis of variance table associated with the fitting of the model.) In some presentations, a scaled form of equation (2), multiplied by n/σ^2 is also seen. This scaled form is called V_x , here.

The Concept of Rotatability

If the variance function $V(\hat{y})$ of equation (2) is a function of r^2 , rather than of the individual x values, in other words, if the variance function depends *only* on the squared distance that the general point $\mathbf{x}$ is from the origin of the design, then the design is said to be a *rotatable design*, one that provides response information of the same precision at all points equidistant from the design origin. One could rotate such a design around the origin to any angle (or equivalently rotate the axes around the origin) and the quality of information obtained on $\hat{y}$ would stay constant on spheres around the design origin. If the model being fitted were first order and the design used were rotatable, we would call the design a *first-order rotatable design*. Similarly, if the model were second order and the design used were rotatable, we would call the design a *second-order rotatable design*. Being rotatable is a very desirable characteristic of the design, but is not an absolutely essential one. However, if we are uncertain (as is typical in much experimental work) in what direction in the predictor space product improvements will be found, it is eminently sensible to gather information that is equally good in all directions at the same distance

2 Rotatable Designs and Rotatability

from the center of the design. Knowing how to attain *exact* rotatability allows an experimenter to obtain a design that is at least *approximately* rotatable while perhaps compromising on other design features. By “approximately rotatable,” an inexact concept here, we mean that contours of the variance function $V(\hat{y})$ may be “almost spherical” but not perfectly so. In picturing variance contours, we could plot the scaled variance V_x directly or, alternatively, plot the so-called information function $I_x = 1/V_x$. Note that when the value of V_x is low (a good feature), the information I_x is high. Figures 1 and 2, reproduced from [1, Chapter 14] and drawn originally by Conrad Fung, show information contours that are not rotatable and fully rotatable, respectively. Figure 1 arises from a 3^2 **factorial** design in two factors (x_1, x_2), indicated by the nine dots. Figure 2 arises from a central composite design (a square, plus four axial points plus four center points; see **Central**

Composite Designs; the four added center points are drawn as separate dots for purposes of illustration only, of course).

Conditions for a Design to be Second-Order Rotatable

Suppose we have n coded design points $(x_{1u}, x_{2u}, \dots, x_{ku})$, $u = 1, 2, \dots, n$ in an experimental design. The quantity

$$\frac{1}{n} \sum x_{1u}^p x_{2u}^q \dots x_{ku}^t \quad (3)$$

(here and below, the summation is taken over the design points $u = 1, 2, \dots, n$) is called a *design moment* of order $p + q + \dots + t$. Then the design is rotatable of second order if and only if, for all i and j , where $i \neq j$, running from 1 through k ,

(a)

(b)

Figure 1 (a) Information surface for a 3^2 factorial arrangement used as a second-order design. (b) The corresponding information contours, formed by taking horizontal slices of (a). The contours are not circles and so the design is not rotatable

Figure 2 (a) Information surface for a cube plus star plus four center points arrangement used as a second-order design. (b) The corresponding information contours, formed by taking horizontal slices of (a). The contours are circles, and the design is rotatable

the following moment conditions (which define the quantities λ_2 and λ_4) hold:

$$\begin{aligned} \frac{1}{n} \sum x_{iu}^2 &= \lambda_2, \frac{1}{n} \sum x_{iu}^4 \\ &= 3\lambda_4, \frac{1}{n} \sum x_{iu}^2 x_{ju}^2 = \lambda_4 \end{aligned} \quad (4)$$

and provided that all other design **moments** up to and including order 4 are zero (see [2, p. 209]). To avoid singularity in the associated regression analysis, the ratio λ_4/λ_2^2 must exceed $k/(k+2)$, but this can always be achieved by adding center points, if needed. These conditions (equation 4) impose restrictive symmetries on the design in all the dimensions $(x_1, x_2, \dots, x_k)$. The relationship in equation (4) between the two types of fourth order moments (that the pure fourth moment must be three times as big as the mixed fourth moment) will be

applied below to achieve rotatability for central composite designs.

Conditions for a Design to be First-Order Rotatable

Only the conditions $\frac{1}{n} \sum x_{iu}^2 = \lambda_2$, plus “all other design moments up to and including order 2 must be zero” are needed. Thus all orthogonal first-order designs with the same pure second-order moment in all dimensions are first-order rotatable.

Some First-Order Rotatable Designs

A sensible design for fitting a first-order model is a two-level factorial or two-level **fractional factorial** of resolution III or better (i.e., of higher resolution)

(see **Factorial Experiments; Fractional Factorial Designs; Main Effect Designs; Plackett–Burman Designs**) Such a design will estimate all first-order coefficients although, in the case of a resolution III design, some or all main effects will be aliased (confounded, confused; see **Aliasing in Fractional Designs**) with possible two-factor interactions that may exist. Such a design is first-order rotatable, that is, it provides information on the first-order response with the same accuracy at the same distance from the center of the design, in other words on circles/spheres about the origin. For a first-order model, any orthogonal design with all pure second-order moments equal to the same number λ_2 , has a diagonal $\mathbf{X}'\mathbf{X}$ proportional to the unit matrix $\mathbf{I}$, except for the first entry, and is first-order rotatable. In fact, if the n design points are at $(\pm 1, \pm 1, \dots, \pm 1)$, then $V(\hat{y}) = \sigma^2(1 + r^2)/n$ and so $V_x = 1 + r^2$.

Rotatability of the Central Composite Second-Order Design Class

In order to fit a second-order model, at least three levels of each x_i must be chosen in forming a suitable design. A popular and practical design choice (see **Central Composite Designs**), which can be found in many published experimental presentations, is the so-called central composite design which provides four levels (or five if, as is usually done, *center points* are added), in general. A central (i.e., centrally located about the coded design origin) composite design consists of three parts:

1. a “cube” part, that is, a two-level n_c points portion $(\pm 1, \pm 1, \dots, \pm 1)$, usually of resolution IV or higher (which means that no **main effect** is aliased with any two-factor interaction); plus
2. a “star” part, consisting of $2k$ axial points of the forms $(\pm\alpha, 0, 0, \dots, 0)$, $(0, \pm\alpha, 0, \dots, 0)$, $(0, 0, \pm\alpha, \dots, 0)$, $\dots$ $(0, 0, 0, \dots, 0, \pm\alpha)$, where α is not yet specified; plus
3. n_0 center points $(0, 0, \dots, 0)$.

(If the star distance is chosen to be $\alpha = 1$, the design is often called a *face-centered central composite design*.)

For such a design, $\sum x_{iu}^2 = n_c + 2\alpha^2$, $\sum x_{iu}^4 = n_c + 2\alpha^4$, and $\sum x_{iu}^2 x_{ju}^2 = n_c$. Thus, to satisfy equation (4), we set $n_c + 2\alpha^4 = 3n_c$, whereupon $\alpha = n_c^{1/4}$. Some examples of this follow, with the asterisk

denoting that a half fraction of the 2^k design is being used as the “cube” portion of the design:

k	2	3	4	5	5*	6	6*
n_c	4	8	16	32	16	64	32
α	1.414	1.682	2	2.378	2	2.828	2.378

As mentioned previously, Figure 2(a) shows a rotatable composite design in two dimensions with four center points; we see now that $\alpha = 1.414 = 2^{1/2}$. (It happens in this case that the noncentral design points lie on a circle, a two-dimensional sphere; this sphericity feature is *not* true for other examples, as we see from the α numbers shown for other dimensions.)

The literature of experimental design has many papers about rotatable designs and rotatability of orders 1–4. See, for example, the bibliography in [1]. All such designs are technically interesting, but some are too big for typical experimental work. For $k = 4$ and 7, useful rotatable designs exist in the series of Box–Behnken three-level designs (see **Box–Behnken Designs** or [1, Chapter 15] or [3]).

Measuring Second-Order Rotatability for a Design

For comparing two or more second-order experimental designs, a *measure of second-order rotatability* might be useful. Several suggestions appear in the literature; see [4–8]. We recommend the measure in [6], because it does not depend on the orientation of the design in the factor space. Comparisons of the recommended measure against competing measures appear in [6, 8].

Higher-Order Rotatability of a Design

If models of third or fourth order were of interest, rotatable designs of those orders could be used. There are a number of papers in this area, listed in the bibliography of [1]. See also [9] and the references therein. However, with rare exceptions, experimenters usually feel that the large experiments required are impractical. It is usually preferable to fit a second-order model in a moderate size area of the predictor variables space, use **ridge** analysis to move to a better area, and then refit a second-order model there to new data from another experiment.

Graphical Assessment of Response Surface Designs

Consider Figure 2(a) again and think of it as a cake. Imagine a conventional triangular slice cut from this cake. The top edge of such a slice will have an I_x profile that could be plotted in two dimensions against the radius $r = (x_1^2 + x_2^2 + \dots + x_k^2)^{1/2}$. Such a curve could be compared with a similar curve of another competing rotatable design. Alternatively, we could plot the inverse function of I_x , namely V_x , in two dimensions and make comparisons on that basis. Such a plot of V_x is called a *variance dispersion graph* (VDG). When the design is not rotatable, the edges of the cake slices will not all have the same profile, of course, but it would still be useful to look at curves of maximum, minimum, and “spherical” average values of V_x versus r to compare designs (see [10, 11]). Such curves also provide a way to compare, for central composite designs (see **Central Composite Designs**), various choices of the star distance α and also the number of center points. For a similar approach using the **mean squared error** of prediction, which includes model **bias** errors as well as variance errors (see [12]).

NORMAN R. DRAPER

Sequential Experimentation

Introduction

R.A. Fisher, the originator of statistical experimental design, once remarked that “The best time to design an experiment is after it’s done”. Wry, but certainly true: the more one knows about what factors are important, what extra-experimental sources of variation might **bias** results, which measurements are difficult to make (i.e., are noisy/imprecise) and which are not – in short, the more one knows about the system under study – the better one can focus an experiment to learn more about it.

There is nothing particularly profound in this, of course. Even the justly maligned but widely used practice of studying many factors by holding all but one constant and varying just this one (OFAT: one-factor-at-a-time experimentation) acknowledges this truism. Each experimental factor is varied to its “optimal” setting, often by looking at whether the last change in the factor made results better or worse. Once the “best” setting for a factor has been found, it is then held there and the next factor of interest is then similarly examined. Of course, “optimal” and “best” must be qualified by scare quotes, as this strategy ignores both experimental noise and the possibility of interactions among the factors, issues that will be discussed further shortly. The bottom line is that more careful approaches are needed.

In any industrial or business process, there are always potentially many factors that might affect the response(s) of interest. The classic **Ishikawa “fish-bone” diagram**, Ishikawa [1], is one well-known quality tool that can be used by those who share process knowledge to identify from dozens to literally hundreds of methodological details, raw material variations, equipment settings, environmental factors, and even maintenance procedures that might impact results.

As a canonical example, consider a measurement process to measure “purity” (of a chemical, food product, or drug, say). Such a process requires a procedure for obtaining and preparing samples to be measured, for storing them over the course of the preparation, to prevent outside contamination or chemical reactions with the environment, and for

obtaining a readout of the prepared samples in an instrument. Typically, the protocols defining these procedures contain many steps – how to sample, how to handle the samples, what reagents to use, what times and temperatures the samples can be stored under, how the instrument is to be set up, calibrated, maintained, and so forth. A long list of individual factors that might affect the process would result.

In reality, for a process to work at all, prior knowledge and experience will generally dictate how to control most, if not all, of these many details satisfactorily. When this is not the case, typically a relatively small subset of process variables – less than, say, 15 or so and perhaps only 1 or 2 – can be identified for empirical investigation and adjustment, that is, experimentation. That is the focus of this article.

If “first principles” and prior experience have whittled the number of process variables down to at most one or two, it is generally not difficult to come up with a reasonably efficient experimental strategy that achieves success. Here, “efficient” simply means with an acceptable expenditure of time and effort. It is important to note, however, that “efficiency” can be defined in a statistical way that formalizes this idea of minimizing experimental effort in order to design “optimally” efficient experiments (*see* **Optimal Design**). While this theory turns out not to be quite so “optimal” in practice, it nevertheless yields very useful insights and approaches that can greatly reduce experimental effort. The strategy of sequential experimentation implicitly uses much of this methodology. So while no claims of statistical optimality will be made, a major advantage of using this approach is that it achieves success with less experimental effort.

But what happens if one cannot identify one or two variables that can be manipulated and cannot achieve a satisfactory result in those that are used. This is often the case, for example, when there are several competing criteria that together constitute “satisfactory” performance: it may be easy to optimize the criteria individually but difficult to find a compromise that is satisfactory for all.

However it comes to pass, when there is a need to investigate the settings of more than just one or two process variables, it is no longer so obvious how to proceed. Following Fisher’s observation, the experimental strategy should be a frugal one. That is, whenever possible (it isn’t always!), one would prefer to gradually accumulate understanding through a sequence of relatively small experiments, rather than

2 Sequential Experimentation

gambling everything on a large, one-shot effort. Not only does this permit later experiments to take advantage of what has been learned, it also allows the experimenter to recover from “mistakes” – misjudgments about what variables should be investigated and over what ranges, for example – before experimental resources (or managerial patience!) have been exhausted. No experimenter who is truly on the frontier of knowledge can avoid making such mistakes, so it makes sense to employ a strategy that quickly reveals and recovers from errors so that more fruitful directions can be pursued.

An Outline of the Strategy

There are three principles that underpin the sequential experimentation strategy.

1. Exploit Occam’s razor, which is an early version (from the fourteenth century English logician and friar, William of Ockham) of the familiar *Pareto principle* that asserts that in any process, about 80% of the process variation is caused by about 20% of the process variables. In this context, it means that one can expect relatively few (sometimes none!) of the experimental variables being considered to meaningfully affect the response. By employing a strategy to efficiently identify and quantify the effects of just these few, one can learn how to achieve the desired performance with great experimental economy. Because time and resources are always limited, this is often crucial.
2. Distinguish signal from noise. To be useful, an experiment must yield results that are replicable. In other words, to infer that observed changes in a response were actually caused by changes in an experimental variable – which can then be used to control the response – those changes must not in fact have been due to uncontrolled and unknown sources of experimental variability. Of course, this is a fundamental precept of science, not merely of statistical experimental design.
3. Allow for interaction (*see Interactions*). Factors often affect results interactively. Example: the concentration of glucose needed for best growth of a cell culture depends on the concentration of certain amino acids present in the growth medium. One cannot specify how glucose affects growth without simultaneously specifying how

much amino acid is present (and conversely). This kind of behavior is clearly not uncommon, and so it is important that multifactor experiments allow for such possibilities (*see Factorial Experiments* for further discussion).

In many respects, these principles seem almost self-evident; but in fact, OFAT experiments violate all of them! They fail the first, because equal effort must be expended to investigate each experimental factor; there is no “information sharing” that allows, for example, *hidden replication* (*see Fractional Factorial Designs*) or elucidation of interactions in the space of *active factors* (various aspects of which are discussed in *Aliasing in Fractional Designs*; *Foldover Designs*; *Fractional Factorial Designs*; *Plackett–Burman Designs*; *Projectivity in Experimental Designs*). They fail the second, because they make poor use of experimental information and therefore are only reliable in sufficiently high signal/noise situations. This can only be achieved by (appropriately!) replicating the individual factor changes a large number of times, thereby incurring excessive experimental effort. They fail the third because interactions cannot be “seen” when only OFAT is changed: by definition, interactions require the simultaneous change of two or more experimental factors to evidence themselves (*see Interactions*).

To gain a rough sense of how ineffective OFAT can be compared to the strategy outlined here, suppose that one has 10 experimental factors to study. By 1, it is reasonable to expect that no more than two or three of them will have large enough effects – either individually or jointly (interactions) – to be of concern. With this in mind, one could use a so-called 12-run Plackett–Burman design (named after the two British mathematicians who discovered it in 1946 – *see Plackett–Burman Designs*), perhaps with a few added center points (*see Center Points*) to determine what the important factors were and how they affect the response of interest. An additional few runs or foldover (*see Foldover Designs*) are occasionally required to resolve possible uncertainties that might exist (e.g., due to aliasing, *see Aliasing in Fractional Designs*). So perhaps 15–20 experimental runs might be required to distinguish the few most active factors (if any!) from noise (2) and gain a general sense of their individual and joint effects (3).

By contrast, to gain the same information on the individual effects using the OFAT strategy, a

minimum of 120 experimental runs (and some center points, perhaps) are required. This is roughly six to eight times the experimental effort! Moreover, even with this large number of runs, there is no information about any possible interactions!

The strategy outlined here was developed over the course of about 70 years (starting about 1920) by Fisher, Frank Yates, Oscar Kempthorne, Gertrude Cox, George Snedecor, George Box, and numerous other statisticians. Interestingly, most of the work prior to 1950 had its roots in agricultural experimentation to improve crop and livestock yields, reduce pests, and so forth. More recent (post-1990) developments by Box, John Tyssedal, Ching-Shui Cheng (*see Projectivity in Experimental Designs*), and others make use of the mathematical properties of Hadamard matrices and other two-level orthogonal arrays (*see Orthogonal Arrays*) originally discovered by the French mathematician, Jacques Hadamard and further developed by Rao and others in the first half of the twentieth century.

The strategy proceeds in stages as follows:

1. Use small two-level screening designs (*see Screening Designs*) to identify the most important few factors of interest and roughly quantify how they affect the response. Fractional factorials (*see Fractional Factorial Designs*) and other designs of projectivity 3 or 4 (*see Plackett–Burman Designs; Projectivity in Experimental Designs*) can be used. Depending on which, full or partial aliasing may require a small number of carefully chosen follow-up runs to resolve any confounding and clearly identify the influential factors. While there is statistical methodology available to guide this choice, for example, using foldover (*see Foldover Designs*) or as in Meyer *et al.* [2] and Box *et al.* [3], in practice, this is rarely necessary. Subject matter expertise and the hierarchy of effects – which asserts that main effects are more likely than two-factor interactions (2 fi's), 2 fi's are more likely than 3 fi's, and so forth – are usually sufficient.
 2. Stage 1 identifies the important factors and quantifies their effects. This provides an approximate direction for improvement that can now be rapidly explored by running several experimental runs in this direction. This is essentially an empirical version of the *method of steepest ascent* (*see Response Surface Methodology*).
- For example, suppose two factors of 10, A and B, have been identified, and the projection of the fitted **response surface** (equivalently, the fitted model coefficients) indicates that the response will improve most rapidly if A is increased and B is decreased in approximately a 2:1 ratio in standardized scaling units (i.e., units in which the ranges of all experimental variables are -1 to $+1$). Suppose the low and high levels of A and B in stage 1 in their natural (unstandardized) units are l_a, l_b, h_a , and h_b respectively, and δ_a and δ_b are $h_a - l_a$ and $h_b - l_b$. Then in stage 2, the values of the other eight experimental factors would be held constant (at the centers of their range or similar “standard” values chosen for economic or other reasons), and A and B pairs of the form $m + t\Delta$ would be run, where $m = ((h_a + l_a)/2, (h_b + l_b)/2)$, the center of the stage 1 design in A and B, and $\Delta = (2\delta_a, -\delta_b)$. To control for the possibility of an additive shift in response between the stages, typically one would include one or more replicates of the center point, $t = 0$, in this sequence. Note that this can be considered a one variable design in the *constructed variable*, Δ . However, unlike OFAT, the variable was constructed based on experiment – it reflects what nature has to say, not prior ignorance.
3. As t is increased, the response may improve for a while, but eventually one will go too far, and it will crash or various physical or economic constraints will make further increments in t impossible. At this point, there are several possibilities.
 - (a) If results are deemed to be satisfactory, you're done: declare victory and move on.
 - (b) A new design region in A and B will have been identified. With A and B at these new levels some of the other eight previously unimportant factors may now have meaningful effects. This is equivalent to the existence of interactions of A and B with the remaining factors over the wider range of A and B from those of stage 1 to the current levels.^a Hence one might wish to return to stage 1 and repeat a screening design in the original factors with A and B either held constant or varied around their new levels.
 4. Stages 1–3 may be repeated until either no further improvement results or other constraints

(technological, economic) prevent further change in the variables. At this point, one will typically have completed a final two-level screening design in the final optimal region and identified a relatively small number of variables that affect the response in this region. At this point, it may be necessary to explore the region of the optimum in greater detail to determine the sensitivity of the response to changes of the critical variables/validate ranges within which to hold these variables to keep the response within desired limits. In currently fashionable language, this would constitute a kind of process *robustness* study (see **Robust Design**; **Tolerance Design**). A wide variety of approaches to do this have been proposed (see **Performance Measures for Robust Design**; **Product Array Designs**; **Tolerance Design**; **Box–Meyer Method for Dispersion Effects**, for example), but the classical and most widely used approach is to add *axial points* to the existing screening design to create a second-order *central composite design* (see **Central Composite Designs**). The fitted response surface can then be both graphically and mathematically explored using, for example, ridge analysis (see **Ridge Analysis in Experimental Design**) to provide often revealing insight into the behavior of the system under study.

A great virtue of this approach is *sequential assembly*, Box *et al.* [3] (see **Central Composite Designs**): the axial and cube portions of the full second-order design comprise separate *blocks* (see **Blocking**), and so any additive shift that may occur is confounded with blocks. Running center points in both the earlier cube portion and the newer axial portion would allow **estimation** of such a shift; but even if this were not the case, both the first- and second-order (including interaction) variable effects would not be corrupted by a systematic shift in response levels. In other words, valid estimates of the effects – and therefore of the response surface – would be obtained even if there were a shift in system behavior between the times the cube portion and axial portion were run. Some of the **robust design** methods – for example, product array designs (see **Product Array Designs**) – that have been proposed do not easily fit into this paradigm and require large designs run *de novo*. While there are certainly situations where this is justifiable,

it may come at a considerable cost. Sequential assembly attempts to avoid those costs.

Although this overall strategy may seem complex, in concept it is actually rather simple. Here is a little constructed example and picture that shows how it works as compared to standard OFAT experimentation. Suppose there is interest in reducing the amount of a certain contaminant – a reaction by-product – that is formed along with the main reaction product in a biochemical reaction. The contaminant is measured as a percentage of the main peak by ion exchange chromatography, and engineers believe that changes (typically reductions) in reaction time and concentration of a reagent should help reduce it. Figure 1 shows a typical OFAT approach: the initial setting has a time of 9.3 s and a concentration of 11.8. The first set of experiments, shown as white circles, vary the time up and down while holding the concentration fixed. The true, but of course unknown to the experimenters, behavior of the system is shown by the shaded contamination contour plot. If results are very precise, these results would show a slight reduction in contamination by reducing the time to about 8.4 s, as indicated by the X on the horizontal line. Then a second set of experiments would be conducted holding the time fixed at this “optimal” value and varying the concentration as shown by the black circles. The optimal concentration would then be found to be about 10.7, indicated by the second X.

While significant improvement results – the off-peak percentage is reduced from around 2.5 to around 1% – one could still clearly do better. Figure 2 shows how. The 2^2 design indicated by the four white circles is run instead. Analysis of these results would show that the best direction for improvement is that indicated by the arrow. A series of subsequent trials in this direction would clearly lead to the optimal region at the lower left. Incidentally, the key feature of this process is that the time and concentration have an interactive effect on the percentage contamination. The 2^2 design can “see” this interaction, but the OFAT experiment cannot.

Of course, there are both variations and enhancements that may be required to handle special situations, some of which will be mentioned in the next section. But these are technical details. One should not lose sight of the fact that the underlying strategy is a straightforward implementation of the three basic principles that are essential to sound and efficient

Figure 1 Graphical representation of a one-factor-at-a-time experiment. First, time is varied holding concentration constant; then concentration is varied holding time at the previously found best setting. This leads to the false optimum indicated by the X on the vertical line

experimentation. This is why the strategy has such wide potential application and value.

Comments and Caveats

Given the development and claims of the preceding section, one may well ask: “If the sequential experimental strategy is so effective, why is it so little used in the world of science and technology (as any cursory review of the literature demonstrates)?” While a full discussion of this point could probably fill several volumes,^b it is perhaps more reasonable to frame the issue in terms of the practical problems that one encounters when trying to execute such a strategy. Here are several that come to mind.

1. Screening designs with many factors are complex and difficult to do. They require that the levels

of many variables be simultaneously changed, which can be difficult or even impossible in practice. For example, in an experiment to investigate the effect of time after addition of a reagent and the temperature at which the next step of a chemical process takes place, an exothermic reaction may make it difficult to cool the solution down to a desired low temperature if the time after the reagent addition is too short. The logistics of executing simultaneous changes in many variables may also be difficult in some situations, especially when programming automation software is involved.

2. Two-level screening designs and steepest ascent cannot be used when there are categorical factors with more than two categories that need to be tested. While there are sometimes screening-type designs that can accommodate this situation

Figure 2 Graphical representation of the sequential experimental strategy. An initial factorial experiment, indicated by the four white circles around the initial setting, shows that the optimal direction of improvement indicated by the arrow. Subsequent experiments in this direction would lead to the true optimum

(see **Orthogonal Arrays**), it is the nature of categorical variables that to understand what happens at any combination of categories, you have to test all possible combinations. For example, to test the possible effects and interactions of fixture type, product type, and bearing material on the performance of an assembly, you have to test all possible combinations of fixture, product type, and bearing material. When there are many such factors with many categories each, factorial experiments (see **Factorial Experiments**) may become large and unwieldy.

3. It can be very difficult to determine workable ranges for all the variables in screening experiments with many factors. One reason for this is

the so-called curse of dimensionality: the volume of the experimental space increases exponentially with the number of variables. So, for example, if one has only two factors to study, in standardized coordinates the corner points where both factors are at their extremes are only about 40% farther from the origin than individual ranges ($\sqrt{2}$ vs 1); but with 10 factors they are more than three times more distant ($\sqrt{10}$ vs 1)! In any real process in which each of the factors are expected to vary more or less randomly and independently within their individual ranges, it is highly unrealistic to expect more than a few of the factors to be simultaneously at one of their extremes. While effects sparsity (i.e., Occam) may be invoked,

in practice such high-order “cube” points are sometimes obviously unworkable. A statistical restatement of this is that high-order interactions are important in this situation. A simple example is when the amounts of two sugars, glucose and mannose, must be varied to determine how to improve the yield of a cell culture. Individually amounts can be zero, but if both are zero simultaneously – the $(-, -)$ level in a simple 2^2 design – the culture cannot grow.

This reasoning suggests that one might want to make the ranges of experimental factors less extreme when there are more of them than when there are fewer. But how much less extreme? And does this exclude settings in which only one or two factors are extreme that should be investigated? See Voelkel [6] for some related ideas. The problem is that there is a lot of volume in which to experiment, and screening designs are very dependent on Occam in such circumstances just to establish workable initial ranges. One approach is to run preliminary experiments at potentially “dangerous” settings, but this can be time consuming and *ad hoc*.

4. One of the cornerstones of experimental design is randomization (see **Randomization in Experimental Designs**). But more often than not it is difficult or impossible to fully randomize. As an example, suppose one is interested in optimizing a plate-based assay for a drug metabolite in blood (these are usually required for **clinical trials** of drugs). Such assays are conducted in 96-well plates, about $10\text{ cm} \times 15\text{ cm}$ in size, in which the wells are arranged in a 8-row $\times$ 12-column matrix. Factors that one would be interested in investigating typically include well-specific components of the biochemistry (pH, buffer type, reagent concentrations) that can be changed well by well within each plate (perhaps with some effort) and plate-specific components like time and temperature of incubation that can only change from one plate to another. It is impossible to fully randomize such experiments, because this would have to occur at the well level, and times and temperatures cannot be changed at that level.

Such an experiment would have to be conducted as a split-plot design (see **Split-Plot Designs**), but with many factors, such designs

are not simple to plan or analyze. When experiments are conducted as split-plot designs but analyzed as if they were completely randomized, it is quite possible to reach incorrect conclusions. For example, conducting a two-level unreplicated **fractional factorial** as a split plot would actually mean that there are no **degrees of freedom** for the main effects of the whole plot factors (however unaliased interactions with subplot factors could be estimated). The simple and appealing graphical analyses described elsewhere in this encyclopedia (see **Half-Normal Plot; Lenth’s Method for the Analysis of Unreplicated Experiments**) are completely inappropriate. By contrast, if sufficient replication is done and main effects predominate, OFAT would work.

5. One of the strengths of screening designs is that they are very efficient: each experimental run provides a lot of information. This is just another way of describing why OFAT designs with many factors require so many more runs to gain equivalent information (and even then only on the main effects). But this blessing of high efficiency can also be a curse: if a run is “lost” due to some kind of experimental glitch – a not uncommon occurrence – a lot of information can be lost with it. Perhaps worse, if some kind of experimental problem leads to a severely corrupted result, *but the experimenter is unaware that this has happened*, the single bad value can distort all the estimates in an unreplicated design. In OFAT, losing a run here or there makes little difference, and a corrupted value can distort only the single factor being varied. When there is less information to be gained, there is less information that can be lost.

This litany of problems may seem to be a fatal indictment of the sequential experimentation strategy. Not so. As indicated above, there are practical approaches to deal with all these issues. But it is important that any exposition or advocacy of statistical experimental design methods deal fully and fairly with the real circumstances that one faces in using them. As a rule, the statistical experimental design literature does not concern itself with such vexing realities. Thus, researchers who encounter them either knowingly or unknowingly when attempting to apply the methods often do not achieve the results that were advertised,

or may even not achieve useful results at all. Attention to detail is key, but without being told about these details, no attention can be paid.

Final Comments

Unfortunately, even this exposition still fails to touch on many important aspects of the sequential design strategy. One of those alluded to in the introduction is that of multiple responses – it is rare that only a single response is of interest; most of the time there are several that “compete” with each other for optimal settings. Often, this is *the* essential problem driving the investigation. Examples: it is easy to increase yield at the **cost of quality** or to improve quality but reduce yield; but it is difficult to do both. It is easy to improve assay precision at the cost of sensitivity or to increase sensitivity at the cost of precision; but it is difficult to do both. One of the real strengths of the sequential design strategy is that it often makes manifest how such trade-offs should be made. Even better, it often provides ways to avoid having to make the trade-offs at all (*see Dispersion Effects; Performance Measures for Robust Design; Product Array Designs; Box–Meyer Method for Dispersion Effects* for some aspects of this in robust design).

Another important omitted issue is the use of response transformations to both simplify the statistical model and provide insight into underlying scientific behavior. Box *et al.* [3, 7] provide details and examples.

Another topic that underlies the practical implementation of experimental design is the interplay among empirical experimentation, theory, and prior experience. Statistical experimental design is usually expository as if all knowledge were in the data, but this is never even close to the case. Experimenters typically work within a firmly established theoretical framework and have a lot of prior experience with the system under study or ones very similar to it. As a consequence, clear results from a well-designed screening experiment often provide sufficient insight to allow the experimenter to cut short further investigation and successfully apply this subject matter knowledge to directly achieve the results that were sought or to recognize inherent constraints that would make further experimentation useless. George Box once described this in an experimental design class

as the ability of statistical design “to catalyze the scientific learning process”. See Box [8] for further discussion.

Finally, like it or not, the strategy of sequential experimentation is inextricably linked to the philosophy of science: how do theory and experiment interact in the “scientific method”? – what constitutes a “replicated” result? – when is a hypothesis confirmed or contradicted by inevitably noisy data? – when is an experimental result sufficiently unexpected to warrant detailed checking or redoing? Because experimentation is an active process to demonstrate **causality** and not merely to assert passive association for the purpose of prediction, it must deal with such questions. This is perhaps the most interesting and even useful aspect of sequential design, because it focuses on how experimentation alters our understanding of how the world works. Unfortunately, such a discussion is beyond the scope of this article, but perhaps this brief mention will pique the reader’s curiosity and stimulate further thought and study.

End Notes

^aAnother equivalent interpretation is that there is meaningful curvature of the response surface over the wider ranges. Interaction is a second-order effect (*see Response Surface Methodology*).

^bIndeed, it already has. See, for example, Kahneman *et al.* [4] and Kuhn [5] for two possible aspects of the issue.

BERT GUNTER

Dispersion Effects

Introduction

Reducing variation in the performance of industrial products and processes has always been a very important goal. Low variation makes processes predictable, reduces costs, and increases customer satisfaction, among other benefits. Accordingly, variation control and reduction have been the aims of many methodologies: from statistical process control (SPC) (*see Control Charts, Overview*) that boomed after the Second World War to robust design (*see Robust Design*). Since the mid 1980s, robust design has received considerable attention both as a research topic and as a widely used methodology, with excellent results in industrial practice.

Essentially, robust design is a cost-effective method of reducing variation and is based on the use of statistically designed experiments to identify controllable factors that affect both the response level *via* so-called location effects and the response variability *via* dispersion effects. Obviously the idea is to use factors having a dispersion effect to reduce the response variation and factors having a location effect to accomplish an on-target process.

What Dispersion Effects Are and Why Factors Can Affect Variability

Let us call Y the quality characteristic of interest and $X_1, \dots, X_k$ the factors that affect Y , which we can control, and which are usually called *control or design factors*.

The response can then be expressed as

$$Y = f(X_1, \dots, X_k) + \varepsilon \quad (1)$$

Where ε is a random variable assuming $N(0, \sigma^2)$, and where σ^2 is caused by variation in a set of factors that escape our control: for example, environmental factors, variation in raw materials, wear from past use, or simply because they are unknown. These factors are called *noise factors*. Let us label them $N_1, \dots, N_l$. The situation is represented in Figure 1.

It is said that X_i has a dispersion effect when changes in its levels affect the size of σ . This may happen thanks to curvatures in the Y surface caused

by interactions (*see Interactions*) between control and noise factors.

Consider, as an illustration, the simple situation with only one control factor (X) and one noise factor (N) as represented in Figure 2. It is easy to see that the effect on Y of changes in N are much bigger when X is at level -1 than when it is at level 1 . In fact when X is at 0.5 , Y is independent of changes in N . It is clear that X can be used to reduce the variation in the response caused by N ; when this happens we say that factor X has a dispersion effect. Of course, in this case, it also has a location effect.

In summary, it is said that a control factor has a dispersion effect if it interacts with one or several noise factors.

Importance of Dispersion Effects and Examples

As pointed out in the introduction, variation reduction has always been an important goal for all types of processes. W. E. Deming (*see Quality Management, Overview*), one of the most prominent management gurus of the twentieth century, is supposed to have said, "If I would have to reduce my message to managers to a few words, they would be two: reduce variability."

MacKay [1] classifies variation reduction approaches into five generic strategies:

- introducing or tightening output inspection
- introducing or improving feedback control
- reducing variation in process inputs
- introducing or improving feed-forward control
- desensitizing the process to input variation.

Obviously the identification of dispersion effects falls into the last category. It should be noted that this is not only the most economical way to reduce variation, but it can also accomplish variation reduction against types of variability impossible to fight by the other four strategies, especially variation in the conditions under which the product will be used.

Box and Jones [2] inspired by the food industry, give a nice example of this last situation. Consider a producer of a cake mix to be sold in a box containing simple instructions. The quality of the cake when made by the purchaser will depend not only on the ingredients (producer's responsibility), but also on

2 Dispersion Effects

Figure 1 Control and noise factor scheme

how closely the baking instructions printed on the box – oven temperature and time of baking – are followed (outside producer’s control). Clearly, in this case the only possible strategy to reduce the variation in the final product quality characteristics is trying to find control factors with dispersion effects; that is, control factors that interact with time of baking or oven temperature.

To further illustrate the importance of dispersion effects and also how to detect them, we briefly present two well-documented and often studied industrial experiments. The first one includes noise factors in the experiment and the second one tries to detect dispersion effects from an experiment originally conducted to study location effects.

Leaf Spring Experiment

Pignatiello and Ramberg [3] reported an experiment in which the goal was to identify process conditions that would consistently produce leaf springs with a free height of 8 in. Four control factors were included in the experiment: furnace temperature (A), heating

time (B), transfer time (C), and hold down time (D). There was also a noise factor: the temperature of an oil quench (O) in which each spring was submersed at the end of the production process. This temperature was impossible to control during normal production process; it changed with the rate and temperature of the springs submersed, unless a costly investment were made to equip the quench with a heat regulation system.

The aim of the experiment was “. . . to find combinations of the levels of control factors that would yield a free height of 8 in. while being insensitive to the quench oil temperature”. The objective could be better expressed as to identify the location and dispersion effects of controllable factors, and use the knowledge gained to design a process that would consistently produce leaf springs with a free height of 8 in.

The experiment conducted was a 2^{4-1} for the control factors and a 2^1 for the noise factor, shown in Table 1. At each factor combination, three springs were produced in a row; notice that they are not real replicates.

Table 2 summarizes the finding regarding location effects.

The analysis presented by Pignatiello and Ramberg for variability is based on Taguchi’s signal-to-noise ratio (SN) (see **Signal-to-Noise Ratios for Robust Design**), which is a statistic that summarizes the results at each control factor setting over the various noise factor settings. As will be seen later, this type of analysis is called *row summary analysis*. Even though, in general, when SN ratios are used it is difficult or impossible to separate location and dispersion effects, in this case they identify factor B (heating time) as having a big dispersion effect and factors A , B , and D as having significant location effects. Similar results would be obtained by using any usual row summary statistics – the variance and several transformations have been proposed – for

Figure 2 Interaction plot showing the dispersion effect of factor X

Table 1 Design matrix and response for the 2^{4-1} by 2^1 experiment

Control factors				Noise factor						Row summary	
A	B	C	D	-1			1			Mean	S ²
-1	-1	-1	-1	7.78	7.78	7.81	7.50	7.25	7.12	7.54	0.090
1	-1	-1	1	8.15	8.18	7.88	7.88	7.88	7.44	7.90	0.070
-1	1	-1	1	7.50	7.56	7.50	7.50	7.56	7.50	7.52	0.001
1	1	-1	-1	7.59	7.56	7.75	7.63	7.75	7.56	7.64	0.010
-1	-1	1	1	7.94	8.00	7.88	7.32	7.44	7.44	7.67	0.090
1	-1	1	-1	7.69	8.09	8.06	7.56	7.69	7.62	7.79	0.050
-1	1	1	-1	7.56	7.62	7.44	7.18	7.18	7.25	7.37	0.040
1	1	1	1	7.56	7.81	7.69	7.81	7.50	7.59	7.66	0.020

the variability. (Table 1 shows the mean and the variance.)

An alternative analysis was conducted by Steinberg and Bursztyn [4] by looking at the design as if it were a 2^{5-1} , and then studying the interactions between the four controllable factors and the noise factor. Notice that the way the design was constructed the control by noise interactions are free of confounding, although the design is of resolution IV. Table 3 summarizes the results.

This type of analysis has several advantages:

- Allows seeing that the noise factor (oil) has a large **main effect**, indicating that uncontrolled variation during production will cause substantial variation in the free height.
- Identifies B and A (not detected before) as having dispersion effects.
- The study of the control by noise interactions gives a lot of information about the process. In

Table 2 Factors with significant location effects

Factors	Estimated effect
Furnace temperature (A)	0.22
Heating time (B)	-0.18
Hold down time (D)	0.1

Table 3 Factors with significant location effects when analyzed as a 2^{5-1}

Factors	Estimated effect
Oil temperature (O)	-0.26
Furnace temperature (A)	0.22
Heating time (B)	-0.18
Hold down time (D)	0.1
Heating time $\times$ oil (BO)	0.166
Furnace temperature $\times$ oil (AO)	0.084

**Figure 3** Control by noise factor interactions

this case, it can easily be seen in Figure 3 that when working with B at a low level the effect of changing the oil temperature level is less than half the effect of doing so when B is at a high level. Factor B has a strong dispersion effect. Factor A also has a dispersion effect but clearly weaker.

A very simple summary of this case would be that it is possible to simultaneously reduce the variability

4 Dispersion Effects

thanks to the dispersion effects of B and to a lower degree of A, and adjust the mean of the leaf spring's height to 8 in, thanks to factor D, which only has a location effect.

The example illustrates how the detection of dispersion effects is an economical alternative to reduce variability caused by known noise factors.

Taguchi's Welding Experiment

Taguchi and Wu [5] report an arc welding experiment conducted at the National Railroad Corporation in Japan. The experiment was a 16-run, 9-factor, 2^{9-5} **fractional factorial** screening experiment. It has become a reference example of the identification of dispersion effects in unreplicated factorials and thus it has been analyzed many times; see for example: Box and Meyer [6] or Bisgaard and Pinho [7].

The aim of the experiment is to obtain maximum tensile strength (the response) with minimum dispersion. As has been said, the experiment has been analyzed many times by different methods, and all of them agree that factors B (drying method) and C (welding material) concentrate much of the action. Then each method claims further discoveries, but for our purposes let us concentrate on this undisputed conclusion.

Figure 4 shows clearly that both factors B and C affect the location and the level of tensile strength; and also that factor C may affect variability; notice that dispersion is bigger when using material SS41 than when material SB35 is used. Due to the fact that this experiment was conducted without noise factors it is impossible to know the noncontrollable factor that interacts with the material type.

In this case factor C has both location and dispersion effects and, unfortunately, it is not possible to use it at the same time to maximize tensile strength and reduce its variability. A compromise has to be found.

The example illustrates that even when the experiment is not replicated and noise factors are not included in the experiment, it is possible to detect dispersion effects. Of course in this case it is impossible to know which noise factors SB35 neutralizes.

Identification and Estimation of Dispersion Effects

In this section we give a summary overview of the different methods to identify and estimate dispersion effects *via* experimental designs. See reference [8] for a broad panel discussion. In general the designs used are two-level factorial designs (*see* **Factorial Experiments**); however, some authors, Taguchi among them, advocate the use of orthogonal arrays (*see* **Orthogonal Arrays**) that include two- and three-level factorial designs as well as designs with factors at two and three levels.

Designs Including Noise Factors

The basic idea is to include noise factors in the experiment, as in the leaf spring example. This implies that the experimenter has a clear idea of the noise factors to be neutralized and controlled during the experiment, even though they are expensive or impossible to control in normal production conditions.

There are two basic ways to include noise factors in the design, namely, product array (*see* **Product Array Designs**) and single array.

Figure 4 The 2^{9-5} welding experiment projected in the B and C factors space

Product Array. The idea is to set up a design for the control factors and another one for the noise factors – both can be highly fractionated (*see Fractional Factorial Designs*) – and then run all combinations of both designs. The leaf spring design (Table 1) was constructed in this way.

Care should be taken in randomizing (*see Randomization in Experimental Designs*) and running the experiment. It frequently happens that due to constraints on the execution of the trial or for economic reasons the experiment is run in a split-plot way, with all the noise factor levels run in succession at the same level of the control factors (*see Split-Plot Designs*), see Box and Jones [2] and Bisgaard [9].

If the design is run in a completely randomized way, then there are two basic methods of analyzing it. Both have been used and briefly described in the leaf spring example, namely, row summary statistics and response modeling.

Row summary statistics. The procedure begins by computing a statistic that summarizes the responses obtained at each control factor setting over the different levels of noise factors. Table 1 shows two row summary statistics, the mean and the variance. Once the so-called row summary statistic has been computed, it is analyzed in the usual way. Many row summary statistics have been proposed, although this method has been shown to lead under certain conditions to wrong or incomplete answers. This was the case in the leaf spring experiment. Regardless of this fact, the method is widely used, in part thanks to its conceptual simplicity – the method's main advantage – and in part because it is the one advocated by Taguchi and his followers. Another disadvantage is that it does not give information on which noise factor is neutralized by which control factor, thus hindering learning from the process.

Response modeling. The idea is to “integrate” control and noise factors in a single-design matrix and model the response as a function of both control and noise factors; this general approach is favored by many authors, see for example Box and Jones [2], Myers *et al.* [10] and Steinberg and Bursztyn [11]. When this is done, the study of the interactions between control and noise factors, especially through plots – as in the leaf spring example – gives information on the factors having dispersion effects as well as on how they neutralize the variability induced by

noise factors. The model obtained can also be used to derive a model for the variance; however, this is a dangerous approach because the model for the variance is very sensitive to the fitted response model.

Single Array. In this case a factorial experiment is set up, taking care that the design will allow for the **estimation**, without any dangerous confounding, of all two-factor interactions between control and noise factors. See Shoemaker *et al.* [12]. This approach is much more flexible in terms of choosing the effects to be estimated, free of unwanted confounding. Wu and Hamada [13] discuss the choice of single array and give tables for their selection. In general, designs produced by the single-array method cannot be analyzed using row summaries – the rows will not be complete – and thus, they have to be analyzed using the response modeling approach.

Replicated Designs Without Noise Factors

Including noise factors in an experiment is often complicated. As has been pointed out, it requires knowing what they are and also being able to control them during the experiment. It seems then that a possible approach is to conduct “conventional” replicates at each control factor combination indicated by the design matrix and let the noise factors act “naturally”.

The problem of this method is, as noted by Steinberg and Bursztyn [4] that – lacking the “exaggeration” of variability introduced by the deliberate variation of noise factors – they require a big number of replicates to be able to detect dispersion effects. And thus they are not, in general, an economically feasible alternative to designs, including noise factors.

Unreplicated Designs Without Noise Factors

Even though it is clear that the information about the variability of the response contained in an unreplicated factorial design is scarce, there have been many proposals to estimate dispersion effects from unreplicated factorial designs (*see Box–Meyer Method for Dispersion Effects; Bergman–Hynén Method for Dispersion Effects*); a general discussion can be found in Brenneman and Nair [14]. In general this approach should be viewed as a way to try to extract information on dispersion effects from an experiment conducted to estimate location effects rather than

a suitable method to use when the objective is to estimate dispersion effects.

All proposed methods are based on the effect-sparsity principle, which states that in general only a few of the factors included in the experiment will affect the response. The main problem with this approach is that, as has been noted earlier for replicated designs without noise factors, letting the noise factors act naturally gives a very poor **power** for detection of dispersion effects. Obviously not having replicates aggravates this problem. A second difficulty is, as pointed by Box and Meyer [6], the inescapable confusion between location and dispersion effects.

Summary

A factor is said to have a dispersion effect when changing it affects the variability of the response, and this happens when it interacts with factors called *noise factors* that cannot be controlled in normal operating conditions. There are several methods and all of them are based on the use of carefully designed experiments to identify and estimate factors having dispersion effects.

The identification and exploitation of control factors with dispersion effects is, in general, the most economical method and in many occasions – when the noise factors cannot be controlled during product use or normal production – the only one available.

Performance Measures for Robust Design

Introducing Taguchi's Signal-to-Noise Ratio and Two-Step Procedures

The objective of robust design (*see Robust Design*) is to find the vector of design variable settings that minimizes the quadratic loss function popularized by Taguchi and Wu [2],

$$L(Y, t) = A_0(Y - t)^2 \quad (1)$$

where A_0 is a constant, Y is the process response, and t the desired target value for Y . The average loss may be decomposed as follows:

$$\begin{aligned} E_{L(Y,t)} &= R(\mathbf{C}) \\ &= A_0 E_{\mathbf{N},\epsilon}(Y - t)^2 \\ &= A_0 [\text{Var}_{\mathbf{N},\epsilon}(Y) + (E_{\mathbf{N},\epsilon}(Y) - t)^2] \end{aligned} \quad (2)$$

where $\mathbf{C}$ is a vector of design variables that can be partitioned into two mutually exclusive parts corresponding to “nonadjustment” factors, that is, $\mathbf{d} = (d_1, \dots, d_p)$, and “adjustment” factors, that is, $\mathbf{a} = (a_1, \dots, a_q)$. Note that this partitioning of design variables is a theoretical ideal, and mutually exclusive groupings may not exist in practice. $\text{Var}_{\mathbf{N},\epsilon}(Y)$ and $E_{\mathbf{N},\epsilon}(Y)$ are the variance and mean of the process response over the random sources of variability represented by $\mathbf{N}$ and ϵ . $\mathbf{N}$ is a vector of uncontrollable “noise” variables (*see Factorial Experiments*) and ϵ represents purely random variation. For ease of notation we will simply write $\text{Var}(Y)$ and $E(Y)$ from here onward.

The adjustment factors making up $\mathbf{a}$ are those that affect the mean, that is, $E(Y)$, independently of $\text{Var}(Y)$, whereas the nonadjustment variables that make up $\mathbf{d}$ are assumed to affect only the variance $\text{Var}(Y)$. Equation (2) indicates that the minimization of average quadratic loss is mathematically equivalent to the minimization of the sum of process variance and the square of the deviation of process mean from the target.

Taguchi [3] introduced a family of performance measures called *signal-to-noise ratios* (SNRs; *see Signal-to-Noise Ratios for Robust Design*) whose specific form depends on the desired response

outcome. The case where the response has a fixed nonzero target is called the *nominal-the-best* (NTB) case and is defined as follows:

$$SNR = 10 \log_{10} \left[\frac{\bar{Y}^2}{S_Y^2} \right] \quad (3)$$

where $\bar{Y}$ and S_Y^2 are respectively the sample mean and variance of the response estimated at each test combination of design variables selected for experimentation. Responses having unique smaller-the-better or larger-the-better targets are respectively called the *STB* and *LTB* cases. We have only presented the formula of the SNR for the NTB case because it most transparently conveys the concept of a “signal”, that is, $\bar{Y}$, being compared to systemic background variability or “noise”, that is, S_Y^2 .

To accomplish the objective of minimal expected squared-error loss for the NTB case, Taguchi [3] proposed the following two-step optimization procedure:

1. Calculate and model the SNRs and find the values of the nonadjustment factor settings, that is, $\mathbf{d}$, which maximize the SNR.
2. Shift mean response to the target by changing the values of the adjustment factor(s) $\mathbf{a}$.

Although he provided a performance measure, that is, the SNR, and a related optimization scheme, that is, the two-step procedure, it was not explained how these two entities collectively achieve the goal of minimizing average quadratic loss.

Relating Performance Measure to Optimization: The Performance Measure Independent of Adjustment (PerMIA)

León *et al.* [1] showed that under certain circumstances Taguchi's use of the SNR, within the context of his two-step optimization procedure, does in fact minimize expected quadratic loss. Specifically this happens when the response conforms to a **transfer function** of the following form

$$Y = E_Y(\mathbf{a}, \mathbf{d})\epsilon(\mathbf{N}, \mathbf{d}) \quad (4)$$

where $\mathbf{N}$ are the noncontrollable noise variables and $(\mathbf{a}, \mathbf{d})$ are the adjustment and nonadjustment factors. They observed that for this class of models, the

2 Performance Measures for Robust Design

SNR of equation (3) can be minimized independently of the mean. This was a rigorous articulation of when the use of Taguchi's SNR within his two-step optimization procedure accomplished the stated goal of minimizing expected quadratic loss. They caution that when a response is not compliant with the functional form of equation (4), the use of the SNR in the two-step procedure of Taguchi does not necessarily minimize expected quadratic loss.

In order to provide a consistent framework within which to employ Taguchi's two-step procedure, they defined a new entity called the *performance measure independent of adjustment*, that is, the PerMIA. The PerMIA is a performance measure, that is, a function, which can be minimized independently of the mean and is specifically defined for the particular class of models being considered. Assuming that a PerMIA can be defined for the situation under consideration, use of a PerMIA within the framework of the two-step procedure guarantees the minimization of expected quadratic loss. This is because, in the first step, settings of the nonadjustment factors are chosen to minimize the PerMIA and, in the second step, the mean is shifted as closely as possible to its target value by choosing corresponding values for the adjustment factors. Because of the defining properties of the PerMIA, the adjustment of the mean in the second step does not affect the value of the PerMIA. When the process under consideration follows the model of equation (4), the SNR of equation (3) is a PerMIA but for other models it is not. This explained why use of the SNR in all situations does not always yield results that minimize the value of expected quadratic loss.

In particular León *et al.* [1] indicate that for an additive transfer function, that is,

$$Y = E_Y(\mathbf{a}, \mathbf{d}) + \epsilon(\mathbf{N}, \mathbf{d}) \quad (5)$$

that $\text{Var}(Y)$ is a PerMIA and should be used in place of the SNR. León *et al.* [1] conclude by proposing a modification of Taguchi's two-step procedure which first finds values of the nonadjustment factors $\mathbf{d}$ which minimize the PerMIA and, conditional on those values of $\mathbf{d}$, finds the values of the adjustment factors $\mathbf{a}$ that minimize expected quadratic loss.

Nair and Pregibon [4] advocate a three-phase process for robust design consisting of exploration, modeling, and optimization. Their performance measure is process response which they assume is a function of the design and noise variables, that is, $\mathbf{C}$ and $\mathbf{N}$

referred to in equation (2). They reduce the robust design problem to minimization of Var_Y subject to the constraint that E_Y is held as close as possible to the target level t .

They suggest that process variance can typically be modeled as a function of adjustment factors ($\mathbf{a}$) and nonadjustment factors ($\mathbf{d}$) as follows:

$$\text{Var}(Y)(\mathbf{C}) = f_1(E(Y)(\mathbf{a}, \mathbf{d}))\epsilon(\mathbf{N}, \mathbf{d}) \quad (6)$$

This model implies that minimization of variance relies primarily on the nonadjustment factors ($\mathbf{d}$) with residual variability determined by the distance between the mean and the target. They recommend a transformation-based approach which allows the separation of the **dispersion effects**, that is, $\epsilon(\mathbf{d})$, and the location effects, that is, $f_1(E(Y)(\mathbf{a}, \mathbf{d}))$. The specific transformation is identified in the exploratory phase with plots of the response data at each treatment combination supplemented with mean–variance plots. Their graphical examination plots the means and variances on a log–log scale which is approximately linear with slope k for the common situation where

$$f_1(E_Y(\mathbf{a}, \mathbf{d})) = [E_Y(\mathbf{a}, \mathbf{d})]^k \quad (7)$$

which represents an important specific case of equation (6). The values of k suggest the appropriate transformation with a value of $k = 0$ indicating a unity transformation due to the lack of a strong relationship between mean and variance.

Box [5] introduced a generalized transformation of response approach that applies to commonly found relations between location and dispersion. We remind the reader that León *et al.* [1] demonstrated that Taguchi's SNR is a PerMIA when Var_Y is proportional to E_Y . Box defines a PerMIA as

$$P(\mathbf{d}) = \frac{\text{Var}_Y(\mathbf{a}, \mathbf{d})}{f_2[(E_Y(\mathbf{a}, \mathbf{d}))]} \quad (8)$$

under the assumption that the function $f_2[(E_Y(\mathbf{a}, \mathbf{d}))]$ can be found for which the resulting PerMIA is a function of only the nonadjustment design variables $\mathbf{d}$. Because $f_2[(E_Y(\mathbf{a}, \mathbf{d}))]$ is not known *a priori*, Box provides a data analytic technique called the λ plot to empirically find it. The λ plot assumes a transformation of the data, that is, $Y^{(\lambda)}$, such that a value of λ that achieves maximum separation of location and dispersion effects of the process response can be graphically identified.

On a strategic level, Box [5] asserted that the two crucial aspects of robust design are the choice of an appropriate performance criterion and its **estimation**. He states that experimentation, use of simple graphical techniques and sequential testing are the best ways to pursue robust design rather than the use of pre-ordained performance criteria such as the SNR. Box also argued that the SNRs for the STB and LTB cases are inadequate summaries of data and extremely inefficient measures of location.

León and Wu [6] extend the work of León *et al.* [1]. The first thing they explain is how a two-step procedure converts a constrained robust design problem into an unconstrained one. They continue by articulating when a simple adjustment of mean to target can be substituted for solving for values of the adjustment variables **a** that minimize expected loss conditional on the values of the nonadjustment variables **d** that minimize the PerMIA. They introduce a corresponding procedure called the *constrained two-step procedure* (C2P) to simplify the identification of a PerMIA and solve the constrained minimization problem with a second step that simply adjusts the process mean.

Lastly, León and Wu [6] cite the fallacy of assuming a quadratic loss function and mention asymmetric losses around a target as one instance where the quadratic loss function is inappropriate. For non-quadratic loss functions they introduce general dispersion, location, and off-target measures for use in a two-step process. This generalization of the loss function and related two-step procedure includes identification of adjustment functions, that is, functions of design factors used to make adjustments of process location. Though Taguchi used the process mean as an adjustment function, they point to the median as a possible alternative. They apply these new techniques in a number of examples featuring additive and multiplicative models with nonquadratic loss functions.

In an extension of León and Wu's discussion of nonquadratic loss functions [6], Moorhead and Wu [7] develop modeling and analysis strategies for a general loss function where the quality characteristic follows a location-scale model. Their procedure adds a third step to the traditional two-step process, an adjustment step which moves the mean to the side of the target with lower cost. Although limited by its need for a location-scale model, this procedure builds upon the familiar two-step procedures used for quadratic functions. An alternative approach for

asymmetric loss that considers both univariate and multivariate cases is presented in Joseph [8].

Concluding Remarks

In defining the PerMIA, León *et al.* [1] provided a unifying framework in which a performance measure explicitly achieves the optimization goal of minimizing expected quadratic loss via the two-step procedures promoted by Taguchi. León and Wu [6] showed how the PerMIA represents a family of performance measures appropriate for nonquadratic and nonsymmetric loss functions as well. Box [5] and others, including Nair and Pregibon [4], Vining and Myers [9], Shoemaker *et al.* [10], Tsui [11–14], Tsui and Li [15], Lunani *et al.* [16], and Bérubé and Wu [17] posit that using process response or its transformation as a performance measure provides a more flexible approach to robust design than the SNR-based techniques of Taguchi.

Product Array Designs

Introduction

Robust parameter design or **robust design** is the centerpiece of Taguchi's systematic approach to quality improvement (*see Robust Design*), and it consists of three major steps. The first step is to identify parameters (or factors) that affect the performance of a system. Taguchi proposed classification of the factors into three types: control factors (or design factors), noise factors, and signal factors. A system with at least one signal factor is referred to as a *dynamic system*. The primary goal of robust design is to find settings of control factors that simultaneously optimize a system's performance and make it robust to variations caused by noise and signal factors. The second step is to investigate the selected factors through experimentation and to identify optimal control settings to achieve the goal of robust design. Statistical design and analysis of experiments play a critical role in this step. The last step is to conduct confirmatory experiments to ensure that, when the optimal control settings are used, the quality of the system under investigation has indeed been improved.

This article gives a brief review of product arrays, which are among the most popular experimental plans in the second step of robust design. Product arrays were originally proposed by Taguchi and were given a different name (i.e. *inner-outer arrays*). Some researchers and engineers use the term *cross* or *crossed arrays*. The name *product array* is used throughout this article. Though Taguchi's original idea of using robust design for quality improvement is widely considered important, many of his proposed methods have been criticized and more efficient and effective alternatives have been developed by statisticians and other researchers in quality engineering. This is also the case with regard to selecting experimental plans for robust design experiments. In this article, both Taguchi's methods and other new alternatives are discussed.

The organization of the article is as follows. The section titled "Product Arrays" first reviews **factorial** designs and orthogonal arrays, and then defines and discusses product arrays. The section titled "Analysis of Parameter Design Experiments" briefly introduces several popular modeling approaches for analyzing data generated from robust design experiments and

discusses the advantage of product arrays from the modeling perspective. The section titled "Optimal Selection of Product Arrays" discusses the optimal selection of product arrays. The section titled "Compound Orthogonal Arrays" introduces compound orthogonal arrays, a generalization of product arrays. The section titled "Product Arrays with Signal Factors" briefly discusses product arrays involving signal factors.

Product Arrays

Factorial Design and Orthogonal Array

Suppose there are k factors with $l_1, l_2, \dots, l_k$ levels, respectively, in an experiment. These factors have in total $l_1 \cdot l_2 \cdots l_k$ different level combinations or settings. If all the settings are used, the experiment is said to have a full factorial design (or a $l_1 \cdots l_2 \cdots l_k$ design). When $l_1 = l_2 \cdots = l_k = l$, i.e. all the factors have the same number of levels, the full factorial design is then said to be an l^k design. For example, when $l = 2$, we have a full factorial 2^k design. After data are collected from an experiment with a full factorial design, the analysis of variance method is often used to assess the factorial effects of the factors, which include main effects, two-factor interactions, and so on (*see Analysis of Variance*). If an effect involves r factors, it is said to be of order r where $1 \leq r \leq k$; a **main effect** only involves one factor, so it is of order 1.

The major advantage of using a full factorial design is that it guarantees the independent **estimation** of all the factorial effects. When the number of factors increases, the full factorial design quickly becomes infeasible. In practice, a subset of the factor settings is usually selected and used in the experiment. The selected subset is referred to as a **fractional factorial design**. In a fractional factorial design, factorial effects become entangled with each other and are not independently estimable. Nevertheless, a fractional factorial design is sufficient for the study of factorial effects of lower order such as main effects and two-factor interactions, when it is judiciously selected and effects of higher order are assumed to be negligible. The orthogonal arrays proposed by Rao [1] are an example of such designs. An **orthogonal array** with N rows, k columns (or factors), and strength t is an N by k array whose rows are the factor settings such that for any t columns, all

2 Product Array Designs

the possible level combinations of the corresponding t factors appear an equal number of times. The orthogonal array is denoted by $OA(N, l_1 l_2 \cdots l_k, t)$. If some of the factors have the same number of levels, they are usually grouped together in the notation. For example, if among the k factors, k_1 factors have s_1 levels, k_2 factors have s_2 levels, and so on, then the orthogonal array is denoted as $OA(N, s_1^{k_1} s_2^{k_2} \cdots, t)$. An $OA(N, s_1^{k_1} s_2^{k_2} \cdots, t)$ is sometimes denoted by $L_N(s_1^{k_1} s_2^{k_2} \cdots)$ when its strength is equal to two. See **Orthogonal Arrays** for more details.

Orthogonal arrays of strength two, three, or four are commonly used in practice. Under reasonable assumptions about higher-order factorial effects, these orthogonal arrays are sufficient for investigating main effects and/or two-factor interactions. For example, if interactions are assumed to be negligible, then an orthogonal array of strength two guarantees the independent estimation of main effects; if interactions between three or more factors are assumed to be negligible, an orthogonal array of strength four guarantees that both main effects and two-factor interactions are estimable. The estimability of an orthogonal array of strength three is between those of strengths two and four. For general results regarding the estimability of orthogonal arrays of strength t , the reader can consult Hedayat *et al.* [2] and Dey and Mukerjee [3].

Orthogonal arrays can be classified into symmetrical arrays and asymmetrical arrays, according to whether the factors have the same number of levels or not. They can also be classified into regular arrays and nonregular arrays. In general, regular arrays can be constructed by defining relations between factorial effects. Regular symmetrical arrays are among the most popular experimental designs in practice. Two examples are 2^{k-p} and 3^{k-p} designs, where k is the number of factors, 2 or 3 is the number of levels and p is the fraction index. The resolution of a regular symmetrical array is defined to be the lowest order of the effects that are entangled or aliased with the grand mean. It can be shown that the resolution is equal to the strength of the array plus 1. Hence, a 2^{k-p} or 3^{k-p} design with resolution R is an $OA(2^q, 2^k, R-1)$ or $OA(3^q, 3^k, R-1)$, respectively, where $q=k-p$. The minimum aberration criterion proposed by Fries and Hunter [4] is generally used to select optimal regular symmetrical arrays (see **Minimum Aberration**). For a comprehensive account of 2^{k-p} and 3^{k-p} designs and extensive tables of optimal designs,

the reader is referred to Wu and Hamada [5]. General orthogonal arrays have also been tabulated; for example, Hedayat *et al.* [2] includes a fairly comprehensive table (i.e. Table 12.7) of orthogonal arrays of strength 2 with up to 100 runs, and Sloane maintains a library of over 200 orthogonal arrays online (<http://www.research.att.com/~njas/oadir/index.html>).

Product Arrays

As discussed in the introduction, there are three possible types of factors present in a robust design experiment. For ease of discussion, we focus on experiments involving only control and noise factors in the sections titled “Product Arrays”, “Analysis of Parameter Design Experiments”, “Optimal Selection of Product Arrays”, and “Compound Orthogonal Arrays”, and briefly discuss the dynamic cases (i.e. those involving signal factors) in the section titled “Product Arrays with Signal Factors”. Product arrays were originally proposed by Taguchi to accommodate control factors and noise factors in robust design experiments.

Suppose there are k control factors and m noise factors in a robust design experiment. Let $OA_c(N_c, \dots, t_c)$ be an orthogonal array for the k control factors. Because the number of levels of each factor can be arbitrary, it is left unspecified in the notation. Denote the i th row (i.e., the i th control setting) of $OA_c(N_c, \dots, t_c)$ as c_i for $1 \leq i \leq N_c$. Then $OA_c(N_c, \dots, t_c)$ can be considered a collection of control settings, that is, $OA_c(N_c, \dots, t_c) = \{c_i : 1 \leq i \leq N_c\}$. Similarly, let $OA_n(N_n, \dots, t_n)$ be an orthogonal array for the m noise factors. Denote the j th row of $OA_n(N_n, \dots, t_n)$ as n_j . Then $OA_n(N_n, \dots, t_n) = \{n_j : 1 \leq j \leq N_n\}$. The two arrays $OA_c(N_c, \dots, t_c)$ and $OA_n(N_n, \dots, t_n)$ are referred to as the *control array* and the *noise array*, respectively. Taguchi proposed the use of the combined settings (c_i, n_j) with $1 \leq i \leq N_c$ and $1 \leq j \leq N_n$ for the robust design experiment. Clearly, these combined settings are the Cartesian products of the control settings of OA_c and the noise settings of OA_n . Therefore, the resulting design is named a *product array*. The product array is denoted by $OA_p(N_c \times N_n, \dots, (t_c, t_n))$, and it is equal to

$$OA_c(N_c, \dots, t_c) \times OA_n(N_n, \dots, t_n)$$

$$= \{(c_i, n_j) : 1 \leq i \leq N_c, 1 \leq j \leq N_n\} \quad (1)$$

In Taguchi's original terminology, the control array, noise array, and product array are referred to as the *inner array*, *outer array*, and *inner-outer array*, respectively. The product array OA_p is indeed an orthogonal array with $N_c N_n$ rows and $k + m$ columns.

We present a real robust design experiment as an illustrative example. A robust design experiment for improving an injection-molding process was reported in Engel [6]. There were seven control factors, namely, cycle time (A), mold temperature (B), cavity thickness (C), holding pressure (D), injection speed (E), holding time (F), and gate size (G), and three noise factors, namely, percentage regrind (a), moisture content (b), and ambient temperature (c). Each factor had two levels labeled -1 and $+1$, respectively. The goal of the experiment was to determine process parameter settings at which percent shrinkage would be consistently close to a target value. A regular 2^{7-4} design with resolution III (i.e. $OA_c(2^3, 2^7, 2)$) was selected as the control array and a regular 2^{3-1} design with resolution III (i.e. $OA_n(2^2, 2^3, 2)$) was selected as the noise array. The product array is $OA_p(2^3 \times 2^2, 2^{10}, (2, 2)) = OA_c(2^3, 2^7, 2) \times OA_n(2^2, 2^3, 2)$, whose layout together with the data generated from the experiment is given in Table 1.

The c_i 's and n_j 's in the above table indicate the control and the noise settings, respectively. The experiment has 32 runs in total and one observation at each combined setting of the control and noise factors.

A robust design experiment using a product array can be conducted in two different ways. First, it can

be conducted as a completely randomized experiment in which the run order needs to be completely randomized and the factors need to be reset after each run. Second, it can be conducted as a **split-plot** experiment in which the run order is subject to some restrictions. For example, when readjusting the control factors means rebuilding a different prototype system, which can be both time consuming and costly, it is practically more appealing to build the prototype system according to a fixed control setting, and then test the system across all the noise settings. Therefore, the control setting will not be reset between these runs. An experiment run in this manner is known as a *split-plot experiment*, and the analysis needs to take account of this structure; for details, see **Split-Plot Designs**, Box and Jones [7], and Bisgaard and Steinberg [8]. Bingham and Sitter [9] studied the optimal selection of split-plot designs for robust design experiments. In the remainder of this article, we focus on completely randomized robust design experiments only.

Compounding Noise Factors

A major criticism on using product arrays for robust design experiments is that their size tends to be large. For a product array $OA_p(N_c \times N_n, \dots, (t_c, t_n))$, the total number of runs is $N_c N_n$. When the number of control and noise factors increases, $N_c N_n$ may become too large for the product array to be practical. Therefore, there is a need to limit the size of a product array. According to Taguchi, robust design needs to investigate as many control factors as possible, so there might not be much room to reduce the size of a control array. Taguchi saw the opportunity

Table 1 Product Array and Shrinkage Data, Injection Molding Experiment

Runs		A	B	C	D	E	F	G	n_1	n_2	n_3	n_4
									a	b	c	
									-1	-1	$+1$	$+1$
									-1	$+1$	-1	$+1$
									-1	$+1$	$+1$	-1
1-4	c_1	-1	-1	-1	-1	-1	-1	-1	2.2	2.1	2.3	2.3
5-8	c_2	-1	-1	-1	$+1$	$+1$	$+1$	$+1$	0.3	2.5	2.7	0.3
9-12	c_3	-1	$+1$	$+1$	-1	-1	$+1$	$+1$	0.5	3.1	0.4	2.8
13-16	c_4	-1	$+1$	$+1$	$+1$	$+1$	-1	-1	2.0	1.9	1.8	2.0
17-20	c_5	$+1$	-1	$+1$	-1	$+1$	-1	$+1$	3.0	3.1	3.0	3.0
21-24	c_6	$+1$	-1	$+1$	$+1$	-1	$+1$	-1	2.1	4.2	1.0	3.1
25-28	c_7	$+1$	$+1$	-1	-1	$+1$	$+1$	-1	4.0	1.9	4.6	2.2
29-32	c_8	$+1$	$+1$	-1	$+1$	-1	-1	$+1$	2.0	1.9	1.9	1.8

of size reduction in the noise array. He proposed to compound noise factors as one hyperfactor and select a small number of representative levels of this hypernoise factor as the noise settings. The success of using compounded noise factors in robust design requires the judicious selection of the hypernoise factor settings as well as domain knowledge and understanding of the noise effects. There has not been much study about this technique in the literature, though it has been occasionally used in practice. One systematic investigation of the advantages and disadvantages of this technique can be found in Hou [10].

Analysis of Parameter Design Experiments

After data are collected from a robust design experiment, statistical methods are used to analyze the data and find the control settings for robust optimization. These methods primarily follow three different modeling approaches, which are the signal-to-noise (SN) ratio modeling approach proposed by Taguchi (*see Signal-to-Noise Ratios for Robust Design*), the location-dispersion modeling approach, and the response modeling approach. Statisticians and researchers in quality engineering have shown that while the SN ratio modeling approach is effective under some scenarios, it can be seriously flawed in other cases. Many close followers of Taguchi's quality philosophy and practice however still solely rely on this approach. Product arrays might have been proposed particularly for the SN ratio modeling approach. Nonetheless, they are also well suited for the other two approaches. This section briefly reviews these three approaches and then discusses the major advantage of product arrays from an analysis perspective.

SN Ratio Modeling

The SN ratio summarizes performance at each possible control setting. The particular SN ratio used depends on the nature of the problem; *see* Phadke [11] or **Signal-to-Noise Ratios for Robust Design** for details. A common goal of robust design is to achieve a particular nominal level and in this setting the SN ratio is defined to be $\eta = \ln(\mu^2/\sigma^2)$, where μ and σ^2 are the mean and variance of the response of the system under study. Suppose an $OA_p(N_c \times N_n, \dots, (t_c, t_n))$ is used in a robust

design experiment and the obtained data are $\{y_{ij} : 1 \leq i \leq N_c, 1 \leq j \leq N_n\}$, where y_{ij} is the observed response at (c_i, n_j) for $1 \leq i \leq N_c$ and $1 \leq j \leq N_n$. From the data, the SN ratio at the control setting c_i ($1 \leq i \leq N_c$) can be estimated by $\hat{\eta}_i = \ln(\bar{y}_i^2/s_i^2)$, where $\bar{y}_i$ and s_i^2 are the sample mean and variance of $\{y_{ij}\}_{1 \leq j \leq N_n}$. It is clear that the use of the noise array in the experiment is to systematically introduce and evaluate variations attributable to the noise factors at different control settings. The SN ratio $\hat{\eta}_i$ reflects the magnitude of the mean response (i.e. the signal) relative to the variation at the control setting c_i (i.e. the noise). Taguchi proposed to select control settings that maximize the SN ratio to make the system robust to the noise factors.

Once the SN ratios $\{\hat{\eta}_i\}_{1 \leq i \leq N_c}$ are available, regression analysis is used to identify the so-called dispersion effects, which are the control effects that significantly affect the SN ratio (*see Dispersion Effects*). In a separate regression analysis using $\{\bar{y}_i, 1 \leq i \leq N_c\}$ as the responses, the control effects that contribute significantly to the response mean can also be identified. Effects that affect the mean response but do not affect the SN ratio are called the *adjustment effects*. For the nominal-the-best problem, Taguchi suggested the following two-step procedure for robust optimization: (a) Select the settings of the control factors involved in the dispersion effects to maximize the SN ratio $\hat{\eta}$; (b) Select the settings of the factors involved in the adjustment effects to bring the mean response on target. The use of this procedure can be justified by the performance measures independent of adjustment (**PerMIA**), which were proposed by Léon *et al.* [12] and further studied by Léon and Wu [13]; *see Performance Measures for Robust Design* for details. The procedure may however fail to identify dispersion or adjustment effects under other scenarios; *see* Bérubé and Wu [14] for a simulation study. Statisticians and probably the majority of researchers in quality engineering seem to agree that the unquestioning use of the SN ratio for robust design is not desirable; more discussions can be found in Nair [15], Steinberg [16], and Wu and Hamada [5].

Location-Dispersion Modeling

Because the success of robust design hinges on the understanding of how control factors affect the mean μ and variance σ^2 of a system's performance, it is

desirable to directly model μ and σ^2 as functions of the control effects. This idea leads to the location-dispersion modeling approach, which fits regression models for $\{\bar{y}_i\}$ and $\{\log s_i^2\}$ separately and uses the resulting models for robust optimization. Modeling of response mean and variance separately, however, suffers from an obvious drawback that the **heteroscedasticity** inherent in the problem has not been taken into account. A more efficient approach is to fit the mean and variance jointly. Such approaches have already been studied in the statistics literature; see Davidian and Carroll [17, 18] and Nelder and Pregibon [19]. Engel [6] proposed a model to jointly fit response mean and variance in robust design, which is $E(y) = \mu = x^\tau \beta$, $\text{Var}(y) = \phi V(\mu, \theta)$, and $\log(\phi) = x^\tau \gamma$, where β and γ are parameter vectors and θ is usually a scalar, and x is the vector of control effects. Engel then proposed the use of either pseudonormal likelihood or extended quasi-likelihood for parameter estimation. The fitted model is then used for robust optimization; see Engel [6] for more details.

Response Modeling

In a robust design experiment, both the control and noise factors are varied systematically and the responses at different combined settings are observed. Therefore, it is possible to directly model the response as a function of all the factorial effects including the control effects, the noise effects, and their interactions. Subsequently, the fitted response model can be used to derive models for the response mean and variance, which can be further used for robust optimization. This approach is referred to as the *response modeling approach*. The response modeling approach was hinted as early as 1985 by Eastering [20], and was investigated in detail by Welch *et al.* [21], Shoemaker *et al.* [22], and Vining and Myers [23].

Let x and z denote the control and noise factors, respectively, and let $f(x)$, $g(z)$, $h(x)$, and $k(z)$ denote vectors of control effects and noise effects accordingly. A general model that relates a response y to the control and noise effects is $y = \alpha_0 + f(x)^\tau \alpha + g(z)^\tau \beta + h(x)^\tau \Gamma k(z) + \epsilon$, where α and β are coefficient vectors, Γ is a coefficient matrix of the interactions between the control and noise factors, and ϵ is a random error. This general model induces the models for the response mean and variance, which are, respectively, $\mu = E(y) =$

$\alpha_0 + f(x)^\tau \alpha$, and $\sigma^2 = \text{Var}(y) = \beta^\tau \text{Var}(g(z))\beta + h(x)^\tau \Gamma \text{Var}(k(z))\Gamma h(x)$. Given the data from a robust design experiment, the coefficients α , β , and Γ can be estimated, using the general response model. Plugging these estimates in μ and σ^2 gives the fitted mean and variance models, which can be further used for robust optimization. The advantage of the response modeling approach is multifold. First, it can reveal how control and noise factors interact with each other to affect a system's performance. Second, more efficient experimental strategies such as combined arrays can be used for robust design. Third, **response surface** methodologies such as sequential design and **central composite** design can be incorporated into robust design. See **Robust Design** for more details on this approach.

Modeling Advantage of Product Arrays

As mentioned earlier, the product structure of a product array makes it possible to calculate the response mean and variance at any control setting. Therefore, it is well suited for the SN ratio modeling approach. As a matter of fact, the product structure has its merits for the other two approaches as well.

For the location-dispersion modeling approach, Rosenbaum [24, 25] showed that a product array $OA_p(N_c \times N_n, \dots, (t_c, t_n))$ with $t_c = t_n = 2$ ensures that variance calculated at each control setting does not confound control-by-control interactions with any control-by-noise interactions. Hence, when modeling variance as a function of control effects, the dispersion effects can be identified. Furthermore, Rosenbaum extended product arrays to compound arrays that have more **power** in finding location and dispersion effects. Compound orthogonal arrays will be discussed in the section titled "Compound Orthogonal Arrays". For the response modeling approach, the advantage of a product array is stated in the following theorem, which is a modified version of Theorem 10.1 in Wu and Hamada [5]. For ease of presentation, both the control and noise arrays of the product array are two-level regular designs.

Theorem Suppose a 2^{k-p} design is chosen for the control array OA_c , a 2^{m-q} design is chosen for the noise array OA_n , and the product array is $OA_p = OA_c \times OA_n = 2^{k-p} \times 2^{m-q}$.

1. If $\alpha_1, \alpha_2, \dots, \alpha_u$ are u estimable control effects in OA_c and $\beta_1, \beta_2, \dots, \beta_v$ are v estimable noise

effects in OA_n , then the factorial effects $\alpha_i, \beta_j, \alpha_i\beta_j$ for $1 \leq i \leq u, 1 \leq j \leq v$ are estimable in OA_p .

2. All the km control-by-noise two-factor interactions are not confounded with other main effects or two-factor interactions.

Part 2 of the above theorem implies that control-by-noise two-factor interactions can be estimated under the assumption that interactions of order higher than two are negligible. This is considered the major advantage of a product array for the response modeling approach.

Optimal Selection of Product Arrays

Owing to the product structure, the estimation properties of a product array are completely determined by those of its control and noise arrays. Control and noise arrays with good estimation properties lead to good product arrays. Therefore, given the size and the numbers of control and noise factors, an optimal product array is the product of a control array and a noise array, which are optimal in their own rights. For regular orthogonal arrays, the minimum aberration criterion is used to define and select optimal designs; and for nonregular orthogonal arrays, minimum aberration type of criteria have been developed lately (for example, see Xu [26, 27]). In practice, many practitioners are not aware of these better designs and still use standard choices such as those advocated by Taguchi. Extensive tables of minimum aberration two-level, three-level, and mixed-level designs with economical size can be found in Wu and Hamada [5], and some optimal nonregular orthogonal arrays can be found in Xu [26, 27].

Compound Orthogonal Arrays

By relaxing the product structure, Rosenbaum [24, 25] proposed compound orthogonal arrays as a generalization of product arrays. Compared with product arrays, compound orthogonal arrays can have higher strengths for given size and better run-size economy for given strengths. A product array $OA_p(N_c \times N_n, \dots, (t_c, t_n))$ is a collection of (c_i, n_j) where c_i and n_j are the i th row and j th row of the control array $OA_c(N_c, \dots, t_c)$ and the noise array $OA_n(N_n, \dots, t_n)$, respectively. Let $c_i \times$

$OA_n = \{(c_i, n_j), 1 \leq j \leq N_n\}$. Then $OA_p(N_c \times N_n, \dots, (t_c, t_n)) = \bigcup_{1 \leq i \leq N_c} c_i \times OA_n$. Clearly when forming the product array, the same noise array is used for each control setting. Rosenbaum suggested that it should be advantageous to relax this restriction and allow the use of different noise arrays at different control settings. For example, at two different control settings c_i and c_j , two different noise arrays denoted by OA_{n,c_i} and OA_{n,c_j} can be considered, where the subscripts c_i and c_j indicate that these arrays depend on the corresponding control settings. The collection of $c_i \times OA_{n,c_i}$ ($1 \leq i \leq N_c$) forms an orthogonal array, which Rosenbaum called a *compound orthogonal array*. Owing to the allowance of using different noise arrays, compound orthogonal arrays provide more flexibility in accommodating control factors and noise factors, which leads to the advantage stated in the beginning of this section.

Rosenbaum proposed various ways to construct compound orthogonal arrays. Hedayat and Stufken [28] and Zhu *et al.* [29] have further studied compound arrays that have optimal estimation properties. Some useful two-level compound orthogonal arrays have been tabulated in these two references. Compound orthogonal arrays have not yet been adopted by practitioners in real robust design experiments.

Product Arrays with Signal Factors

As mentioned in the introduction, a system with at least one signal factor is referred to as a *dynamic system*. Taguchi [30] referred to the robust design of such systems by the term *dynamic problems*. The focus of a dynamic problem is to optimize the relationship between a system performance measure and the signal factor and simultaneously make the relationship robust to the noise factors. Taguchi defined the dynamic SN ratio and proposed its use for robust optimization of dynamic systems. This can be considered a generalization of the SN ratio modeling approach discussed in the section titled “SN Ratio Modeling”. The response modeling approach has also been developed for dynamic problems by Miller and Wu [31]. Other analysis methods for dynamic problems can be found in Grove and Davis [32], Lunani *et al.* [33], and McCaskey and Tsui [34]. See **Signal–Response Systems** for more details on dynamic systems.

The product arrays discussed in the previous sections do not include signal factors. There are three

possible methods to incorporate signal factors in a product array. For ease of discussion, we assume there is only one signal factor, denoted by G . The first method is to cross a product array OA_p of control and noise factors with G , which leads to an orthogonal array $OA_p \times G$. In other words, for each combined setting of the control and noise factors, the system is tested across the experimental levels of G . The second method is to add the signal factor to the noise array, which leads to a noise–signal array $OA_{n,g}$; and then it is crossed with a control array to generate a product array $OA_c \times OA_{n,g}$. This way was suggested by Taguchi and was often used in practice. The third method is to add the signal factor to the control array, which results in a control–signal array denoted by $OA_{c,g}$; and then it is crossed with the noise array to generate a product array $OA_{c,g} \times OA_n$. There does not exist much study on optimal selection of product arrays involving signal factors, especially for the last two types. See Wu and Hamada [5] for more discussions.

Robust Design

Introduction

Robust design is a methodology by which the controllable factors (inputs) of a system are set in order to achieve consistent and desirable response (output) from the system. The defining characteristic of robust design is the emphasis on achieving a consistently desirable response, not just a response that is desirable on average. “Robust” in this context means “insensitive” or “unaffected” and thus the goal is to find settings of the controllable factors of the system that produce results that are not only desirable but also unaffected by environmental variation or by simple repeated use of the system. Here a brief introduction and tutorial of robust design will be given. More extensive reviews of robust design methodology and literature can be found in Ankenman and Dean [1], Steinberg [30], Wu and Hamada [35, Chapter 10], and Box, Hunter, and Hunter [9, Chapter 13].

In the statistical literature, robust design is a natural successor to response surface methodology (RSM) (see **Response Surface Methodology** and [24]). Box and Wilson [10] wrote the seminal paper for RSM and its title was “On Experimental Attainment of Optimum Conditions”. In that paper, as with most of the literature on RSM, the focus was on optimizing the expected value of the response. Specifically, they strove to maximize the expected yield of a chemical process. Conceptually, robust design can also be thought of as experimental attainment of optimum conditions, where the optimization now includes not only achieving a desirable expected value of the response but also achieving low variance of the response over time and across all environmental conditions that are likely to occur.

The high-level procedure of robust design follows the same basic set of steps as RSM, it is only the specific design and analysis methods that must change due to the emphasis on robustness. The high-level procedure, applicable for both RSM and robust design, involves four basic steps. Step 1 is to study the system to determine the factors (inputs) and response (output) of interest. Step 2 is to design experiments to develop a model of the output as a function of the factors. Step 3 is to analyze the data

from the experiments. Step 4 is to set the controllable factors to desirable settings. The procedure may iterate through steps 1–3 several times before a final decision is reached for step 4.

For clarity, a simple manufacturing example will be used. Suppose that a plastic structural beam is produced by extrusion followed by a knife cut. See Figure 1 for a diagram of the system.

Robust design procedure for the plastic beam example:

- Step 1: Factor and response identification.
Initially, one might identify the factors of interest to be (x_1) knife speed, (x_2) knife temperature, (x_3) extruder screw speed, (x_4) knife position (distance from extruder die), (z_1) ambient temperature, (z_2) percentage of recycled plastic in the material, (z_3) barrel temperature of the extruder, and potentially many more. There could be many responses of interest such as the throughput of the system, the length of the beam, or the surface roughness of the end of the beam where the knife cuts off the extrusion. For this example, the surface roughness of the end, (y) , will be used as the response of interest. And clearly, lower roughness is better.
- Step 2: Experimental design.
After selecting the factors of interest, experiments need to be designed that allow for modeling of the roughness with respect to the factors. The experiments will involve setting the factors at various levels and then producing a number of beams at each of these conditions.
- Step 3: Data analysis.
After data are collected (measurements of the surface roughness of the beams produced in the experiments), the roughness and the variability of the surface roughness are modeled as a function of the factors.
- Step 4: Factor setting.
Given the models created in step 3, settings of all controllable factors should be selected to produce consistently low surface roughness at the end of the beams.

Since step 1 is concerned with the specific knowledge of the system in question and step 4 is a direct result of the models developed in step 3, the

Figure 1 An extruder and knife system for producing a plastic structural beam

robust design literature is essentially the development of specific methods for steps 2 and 3. In the robust design literature, there are two branches of methodology.

The first branch of methodology, called here *robust design for variability from replication*, is used when the variability of interest is caused by mere repeated use of the system. In this scenario, the experimental design techniques are relatively simple. Typically, the designs used are standard first- or second-order experimental designs that are replicated multiple times. After the experiment is run, separate models for the mean and variance of the response are created as functions of the factors in the experiment (see [34]). Numerical optimization methods are then used to determine the settings of the factors that achieve a good balance between achieving a desirable mean response and minimizing the response variation (see [12 or 18]).

The second branch of methodology, called here *robust design for variability from experimentally controllable noise factors*, is used when there exist experimentally controllable noise factors in the system. To understand noise factors, it is first important to understand design factors (sometimes called *control factors*). *Design factors* are factors that are controllable by the system designer. The levels of these factors are not subject to (much) variability during the experiment or even when the system is put into its standard operation mode. For example, in the plastic beam experiment the speed of the knife blade is controlled by a servomotor and can be set with considerable accuracy; thus, knife speed would be considered a design factor. *Noise factors* are factors that affect the response of interest but are randomly varying during the standard operation of the system. In the plastic beam experiment, although the barrel

temperature of the extruder may be affected by various zone temperature settings, it may vary randomly due to other uncontrollable influences that are present both during the robust design experiment and during typical use of the extruder. This would make it a noise factor, but since it cannot be controlled it simply adds to the replication error of the response. *Experimentally controllable noise factors* are factors that, although randomly varying during typical use of the system, can be controlled during the experiments in robust design procedure (Step 2). Again using the plastic beam example, the percentage of recycled plastic might be able to be controlled during the robust design experiment. However, as the process is put into production, this percentage may be subject to random variation from the plastic supplier. If this is the case, then the percentage of recycled plastic is an experimentally controlled noise factor and one of the goals of the robust design procedure would be to make the surface roughness “robust to” (i.e., “unaffected by”) the percentage of recycled plastic in the raw material. Since it can be controlled during the experiment, this factor can be included in the model for the mean and the variance of the surface roughness.

In the next two sections, each of these two branches of robust design methodology is described and explained. Each section begins with a model and proceeds to discuss experimental design and analysis techniques that are appropriate to accurately fitting that model and then using the fitted model to achieve a robust design.

Robust Design for Variability from Replication

When there are no experimentally controllable noise

factors in a system, the most reliable way to measure the variability of the system is to run replicate trials at the various settings of the design factors in the experiment. There are a few available methods for estimating variability without replication (*see Bergman–Hynén Method for Dispersion Effects; Box–Meyer Method for Dispersion Effects*). These methods are less reliable, but can be used if the experimental budget precludes the use of replicates. The goal of robust design in this scenario is to find settings of the design factors that allow for a desirable mean response with low variability. In a typical RSM procedure, the mean response is assumed to depend on the factors, but the variability of the response is assumed to be constant. If these assumptions hold, setting the factors to optimize the mean is in fact the best choice since variability cannot be minimized. However many engineers, most notably Genichi Taguchi (*see* [32]), recognized that often the variability of the system also depends on the design factor settings (*see Dispersion Effects; Performance Measures for Robust Design*). As this became more widely considered, it became clear that the variability of the system can cause substantial quality problems even when the mean response is optimized. This led to the explosion of interest and literature on the robust design procedure.

Since the robust design procedure calls for both the mean and the variability of the response, say y , to depend on the levels of k design factors, the model for the i th response in a robust design experiment is as follows:

$$y_i = \mu(\mathbf{x}_i) + \sigma(\mathbf{x}_i)\varepsilon \quad (1)$$

where $\mathbf{x}_i$ is a k vector such that the j th element of $\mathbf{x}_i$ is the level of the j th design factor in the i th experimental trial, $\mu()$ and $\sigma()$ are unknown functions, and ε is a random error term that follows a standard **normal distribution** (i.e., $\varepsilon \sim N(0, 1)$). Often, $\mu(\mathbf{x}_i)$ is modeled as a first-order linear model so that $E(y_i) = \mu(\mathbf{x}) = \mathbf{x}'\boldsymbol{\beta}$, where $\boldsymbol{\beta}$ is a k vector of parameters. Specifically, the j th element of $\boldsymbol{\beta}$, β_j , is the increase (or decrease if $\beta_j < 0$) in the expected value of the response as factor j is increased by one unit; this is called the *location effect of factor j* . This model is easily extended to a second- or higher-order model by adding additional terms as linear regressors. Since factors are often thought to have a multiplicative effect on the standard deviation of the response, the model $\text{Sdev}(y_i) = \sigma_i(\mathbf{x}_i) = \exp(\mathbf{x}_i'\boldsymbol{\gamma})$

is often used to express the dependence of the variability of the response on the factors (*see Dispersion Effects; Generalized Linear Models* for other models of variance effects, often called *dispersion effects*). Here $\boldsymbol{\gamma}$ is a k vector of parameters where the exponential function of the j th element, $\exp(\gamma_j)$, is the factor by which the standard deviation of the response increases (or decreases if $\gamma_j < 0$) as factor j is increased by one unit; this is called the *dispersion effect of factor j* . For example, if $\exp(\gamma_2) = 3$, then the standard deviation of the response would triple each time factor 2 is increased by one unit. If $\exp(\gamma_2) = -3$, then the standard deviation of the response would be reduced to a third of its value each time factor 2 is increased by one unit. (For notational convenience, $\mathbf{x}$, $\boldsymbol{\beta}$, and $\boldsymbol{\gamma}$ are expanded to $k + 1$ length vectors by including a 0th term; β_0 , and γ_0 represent the constant terms in the linear models and $x_0 = 1$.)

In this scenario, standard response surface designs such as fractional factorials or central composite designs (*see Fractional Factorial Designs; Central Composite Designs*) are appropriate since the primary requirement of the design is that it supports the linear model being fit. If a first-order model is being fit, a two-level resolution III or IV **fractional factorial** design is typically recommended (*see Factorial Designs, Resolution of* and [24], p. 179). If a second-order model is being fit, a central composite or Box–Behnken design is typically recommended (*see Box–Behnken Designs; Central Composite Designs*; and [24], pp. 321–350). One of the considerations in choosing the design is that each design point will need to be replicated to support the model for the standard deviation. Unless the experimental budget is very tight, running only two replications is not recommended as the estimates of the standard deviation at each design point will be very poor. Typically, between three and five replications are taken. More may be needed if the random error is very large.

By selecting only the design factors for the plastic beam experiment, a simple example of robust design for variability from replication can be constructed. If a first-order model is to be fit for both the mean and the standard deviation of the surface roughness, then a four factor, resolution IV, fractional factorial with eight design points could be run and replicated three times as shown in Tables 1 and 2. The high and low levels of each factor are represented by +1 and -1 respectively. The surface roughness data provided are

4 Robust Design

constructed for the purpose of demonstration and thus no units are given.

The analysis begins by calculating the row averages and natural log of the row standard deviations across the three replications for each of the eight design points or *trials*. Standard linear regression can be used to fit the average response vector, $\bar{\mathbf{y}}$, to the expected value model, $\bar{\mathbf{y}} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}_M$, and then to fit the natural log of the standard deviation to the variability model $\ln(\text{Stdev}(\mathbf{y})) = \mathbf{X}\boldsymbol{\gamma} + \mathbf{e}_{sd}$, where $\mathbf{X}$ is the design matrix shown in Table 1 with an additional column of ones appended for the constant, $\mathbf{e}_M$ and $\mathbf{e}_{sd}$ are random error vectors. In this case, the estimates for the location and dispersion effects are $\hat{\boldsymbol{\beta}}' = (79.40 \ -2.58 \ -8.40 \ -0.32 \ 2.10)$ and $\hat{\boldsymbol{\gamma}}' = (-0.23 \ -1.07 \ -0.01 \ -0.03 \ 1.06)$, respectively.

Deciding which of these effects are statistically significant can be a challenging problem. The simplest analysis is to assume that $\mathbf{e}_M$ and $\mathbf{e}_{sd}$ are normally distributed and then to use either a “normal plot of effects” (see **Half-Normal Plot**) or some version of Lenth’s method (see **Lenth’s Method for the Analysis of Unreplicated Experiments** and [36]) to select the significant effects for each model. The

normal plot of effects method is simply a normal **probability plot** of all estimable effects (including estimable interactions, see **Interactions**). Any factor effect that is significantly different than zero will appear as an **outlier** on this normal plot (see [8] pp. 128–131). In Figures 2 and 3, the normal plot of effects for the location and dispersion effects are shown. The literature, notably Nair and Pregibon [26], Vining and Myers [34], Nelder and Lee [27], and Engel and Huele [14], provides a number of more sophisticated methods for determining the significance of the effects that do not necessarily assume normally distributed error and account for the fact that the common regression assumption of constant variance of observations is violated if there are any significant dispersion effects. These methods are very worthwhile if there are no obvious conclusions that can be drawn from the simple normal plotting method. However, if the normal plot method provides very clear delineation of significant location and dispersion effects, it is unlikely that any of these more sophisticated methods will come to substantially different conclusions.

In this example, chiefly because it is contrived, conclusions are easily obtained and it can be seen that factors 1, 2, and 4 have significant location effects, and factors 1 and 4 have dispersion effects. Knife speed (x_1) has a negative effect on both the surface roughness and the variability of the surface roughness and thus should be set to its high level. Since variability of a response is often positively correlated with the mean of the response, it is common to have factors that have both a location and a dispersion effect. Knife temperature (x_2) should clearly be set to its high level since it has a negative effect on the surface roughness and seems to have little, if any, effect on the variability. The knife position (x_4) is a

Figure 3 A normal plot of the dispersion effects

particularly interesting effect since it has a positive effect on variability, but no significant effect on the expected value of the surface roughness. Clearly then, it should be set at its low level to reduce the variability. The extruder screw speed (x_3) has little or no effect on surface roughness or its variability. This factor should probably be set the high level to increase production rate.

In many cases, especially when using second-order models, the proper factor settings for optimizing both

mean and variability are not so clear. In fact, many times setting a factor to its high level may improve the location of the response mean but also increase the variability. In such cases, trade-offs must be made to find factor settings that give a desirable mean response and still reduce variability. Once again there is a substantial literature not only on how to formulate the trade-off problem, but also what algorithms will efficiently and effectively find good or even optimal solutions to the problem posed.

6 Robust Design

Formulation of the trade-off problem depends heavily on whether the response is “the smaller, the better” (as in the case of surface roughness), “the larger, the better” (as in the case of throughput of the system), or “target value is best” (as in the case of length of the plastic beam). In Vining and Myers [34], the first paper to formally pose the problem in this way, they chose the following formulations:

1. “The smaller, the better”: minimize $\mu(\mathbf{x})$, subject to $\sigma(\mathbf{x}) = \sigma_0$, where σ_0 is chosen to be acceptably small.
2. “The larger, the better”: maximize $\mu(\mathbf{x})$, subject to $\sigma(\mathbf{x}) = \sigma_0$, where σ_0 is chosen to be acceptably small.
3. “Target value is best”: minimize $\sigma(\mathbf{x})$, subject to $\mu(\mathbf{x}) = \mu_0$, where μ_0 is the target value.

They show how an optimization method provided by Myers and Carter [22] can provide solutions to the posed problems. Subsequent to this paper, many authors weighed in not only on the formulation of the problems but also on various mathematical programming techniques for solving these problems. Examples of these papers are Del Castillo and Montgomery [13], Lin and Tu [19], Copeland and Nelson [11], Kim and Lin [17], Del Castillo, Fan, and Semple [12], Fan [15], Tang and Xu [33], and Köksoy and Doganaksoy [18].

Robust Design for Variability from Experimentally Controlled Noise Factors

When noise factors (which by definition are uncontrolled in the standard operating conditions of the

system) can be controlled in a robust design experiment, a different set of experimental design and analysis tools are needed to achieve steps 2 and 3 of the robust design procedure. These tools focus on reducing the variability of the response that is related to the uncontrolled variability of the noise factors during the standard operation of the system (i.e., after the robust design experiment is finished and the system is returned to a production mode.)

Again, Genichi Taguchi (see [31]) was the person who recognized that including noise factors in the experiment allows for design factors to be set not only to optimize the mean response, but also to minimize the variability of the response due to those noise factors. He called this practice *parameter design*, but here it is called *robust design*. A simple way to think about robust design with noise factors is to study the experimental design recommended by Taguchi (and many others) for these experiments (see Table 3). Taguchi advocated what is called an inner and outer (sometimes called *product* or *crossed*) array design (see **Product Array Designs**). This design begins by separating the noise factors from the design factors and creating an experimental design (usually an **orthogonal array**) for only the design factors. Taguchi calls this the *inner array* or *design array* and it can be thought of as a representative sample of the possible designs that could be chosen for the system. The design factors are listed in columns so that each design point in the inner array corresponds to a row. Next, a separate *outer array* or *noise array* is constructed for the noise factors. The outer array can be thought of as a representative sample of all likely noise conditions (levels of the noise factors) that the system is likely to encounter in its standard operation. Each noise factor appears in a row so that

Table 3 A crossed (inner and outer) array experiment

8	+1	+1	+1	+1		65.0	67.1	79.7	80.4	73.1

each design point in the noise array is a column. The overall design is setup like a matrix of observations that runs the entire outer array for the noise factors at each design point for the design factors in the inner array. In the plastic beam example, (z_1) ambient temperature and (z_2) percentage of recycled plastic in the material are both subject to variability in the actual process, but will be controlled noise factors in the experiment. Table 3 shows an inner and an outer array design that could be used for this robust design experiment. The observations are shown in the table. So for example, 65.0 is in the last row and the first column and it is the surface roughness observation for a beam that was produced with all the design factors at their high level and all the noise factors at their low levels. As in the previous section, the surface roughness data provided are constructed for the purpose of demonstration and thus no units are given.

By looking at the crossed array experiment, one can easily visualize the goal of a robust design experiment that includes noise factors. Specifically, the goal is to choose settings of the design factors that give a consistently desirable response across all noise conditions (a row of observations). It is possible to treat this problem in the same way as the “robust design for variability from replication”, and try to simply minimize the standard deviation across all the noise conditions while setting the mean response to a desirable value. However, calculation of a standard deviation across a row implies that observations in the row are random draws from a stable distribution. This is clearly not true since the settings of the noise factors are not randomly chosen, but intentionally set to various high and low levels across the row. Thus, calculating a standard deviation discards the information that is available about the levels of the noise factors for each of these four trials in the row.

A better analysis is offered by a model of the response with respect to both control and noise factors. This approach can be found in Shoemaker *et al.* [29], Myers *et al.* [23], Lucas [20], and Myers *et al.* [25]. Since the noise factors will not be under the control of the designer in the standard operating mode of the system, the noise factors in the model must be treated in a different way. In particular, the level of each noise factor in standard operating mode can be thought of as a random variable with some distribution. Historical data can be used to determine a model distribution for each noise factor. Adding the noise factors to the model for the

experimental data gives the following:

$$y_i = \mu(\mathbf{x}_i, \mathbf{z}_i) + \sigma(\mathbf{x}_i, \mathbf{z}_i)\varepsilon \quad (2)$$

where $\mathbf{z}_i$ is a k vector such that the t th element of $\mathbf{z}_i$ is the level of the t th noise factor in the i th experimental trial. Although other models are possible, a first-order model with two-factor interactions is the most common model to be used for robustness experiments. This is primarily due to the key role of design-by-noise factor interactions. To highlight this role, the model with k design factors and m noise factors will be written as follows:

$$\begin{aligned} y = & \beta_0 + \sum_{s=1}^k \beta_s x_s + \sum_{s=1}^{k-1} \sum_{t \neq s} \beta_{st} x_s x_t + \sum_{t=1}^m \alpha_t z_t \\ & + \sum_{s=1}^{m-1} \sum_{s \neq t} \alpha_{st} z_s z_t + \sum_{s=1}^k \sum_{t=1}^m \lambda_{st} x_s z_t + \sigma(\mathbf{x}, \mathbf{z})\varepsilon \end{aligned} \quad (3)$$

where the λ_{st} parameter is associated with the interaction between the s th design factor and the t th noise factor. There is a β parameter associated with each **main effect** and each two-factor interaction for the design factors and an α parameter associated with each main effect and each two-factor interaction for the noise factors. When noise factors are included in the robust design experiment, it is often thought that these noise factors are the primary causes of variability. Therefore, it will be assumed here that when noise factors are included in the experiment, the random error does not depend on the factor levels (i.e., $\sigma(\mathbf{x}_i, \mathbf{z}_i) = \sigma$). In operating mode, each noise factor, z_t , will have a variance, $\text{Var}(z_t)$. For ease of discussion, it will be assumed here that noise factor distributions are independent of each other (so that $\text{Cov}(z_s, z_t) = 0$ for all s and t) and that none of the noise factors interact with each other (i.e., $\alpha_{st} = 0$ for all s and t). Thus, the variance of the response can be expressed as:

$$\begin{aligned} \text{Var}(y) = & \text{Var} \left[\sum_{t=1}^m \alpha_t z_t + \sum_{s=1}^k \sum_{t=1}^m \lambda_{st} x_s z_t \right] + \sigma^2 \\ = & \text{Var} \left[\sum_{t=1}^m \left(\alpha_t + \sum_{s=1}^k \lambda_{st} x_s \right) z_t \right] + \sigma^2 \\ = & \sum_{t=1}^m \left(\alpha_t + \sum_{s=1}^k \lambda_{st} x_s \right)^2 \text{Var}(z_t) + \sigma^2 \end{aligned} \quad (4)$$

From equation (4), it can be seen that if there are no design-by-noise factor interactions, (i.e., $\lambda_s = 0$ for all s), then the variance of the response does not depend on the design factor settings ($\mathbf{x}$). Thus, without design-by-noise factor interactions, all settings of the design factors are equally robust to the noise factors and the design factors should be set to optimize the mean response as in traditional RSM.

However, if there are design-by-noise factor interactions (i.e., $\lambda_s \neq 0$ for some s), then there must exist some set of design factor settings that reduce the variance of the response. For example, if there exists a set of design factor levels ($x_1, x_2, \dots, x_k$), such that $\sum_{s=1}^k \lambda_{st} x_s = -\alpha_t$ for each t , the variance of the response is reduced to σ^2 , the replication error. Since the existence of design-by-noise factor interactions is critical to reducing variability, the focus of robust design experiments is often heavily focused on **estimation** of these particular interaction effects.

In addition to the robustness, the mean or average response is also of interest. Taking the same assumptions as before (i.e., $\text{Cov}(z_s, z_t) = 0$ and $\alpha_{st} = 0$ for all s and t), and letting the noise variables be coded such that the mean value in production mode is 0 (i.e., $E(z_t) = 0$), then the expected value of y is as follows:

$$E(y) = \beta_0 + \sum_{s=1}^k \beta_s x_s + \sum_{s=1}^{k-1} \sum_{t \neq s} \beta_{st} x_s x_t \quad (5)$$

Optimization techniques can again be used to search for the settings for the design factors that will produce a desirable mean response with low variability (see [21, 28]). For example, suppose that we wish to solve the problem in equation (6) for the plastic beam example, where y represents the surface roughness:

$$\begin{aligned} \text{Minimize}_{\mathbf{x}} : \quad & E(y) = \beta_0 + \sum_{s=1}^k \beta_s x_s + \sum_{s=1}^{k-1} \sum_{t \neq s} \beta_{st} x_s x_t \\ \text{Subject to :} \quad & \text{Var}(y) = \sum_{t=1}^m \left(\alpha_t + \sum_{s=1}^k \lambda_{st} x_s \right)^2 \\ & \times \text{Var}(z_t) + \sigma^2 \leq \sigma_0^2, \text{ where } \sigma_0^2 \\ & \text{is chosen to be acceptably small.} \end{aligned} \quad (6)$$

To solve equation (6), estimates for the variance of the noise factors in standard operating mode must be

obtained from historical data. In addition, the robust design experiment must provide estimates of the α , β , and λ parameters. A more in-depth discussion of the issues of experimental design will be given later, but note for now that a crossed array can provide estimates of all these parameters as long as the design array is of at least resolution V and the noise array is of resolution III. If interactions among the design factors are believed to be unimportant (i.e., $\beta_{st} \approx 0$ for all s and t), then a design array of resolution III is sufficient.

In the plastic beam example, it will be assumed that the only interactions are design-by-noise interactions. To estimate parameters from the robust design experiment, the regression model $\mathbf{y} = \mathbf{W}\boldsymbol{\theta} + \boldsymbol{\epsilon}$ is used, where $\boldsymbol{\theta}' = (\boldsymbol{\beta}' \boldsymbol{\alpha}' \boldsymbol{\lambda}')$ and $\mathbf{W}$ is a 32×15 linear regression model matrix that is a function of the design array and the noise array. It has 32 rows corresponding to the number of observations in the crossed array. It has one column of ones for the constant, a column for each of the four design factors, a column for each of the two noise factors and a column for each of the eight design-by-noise interactions. More generally, let k and m be the number of design factors and noise factors respectively and let p and q be the number of design points in the design and noise arrays respectively. The $\mathbf{W}$ matrix is a $pq \times (1 + k + m + km)$ made up of four parts as follows $\mathbf{W} = [\mathbf{1} \ \mathbf{X} \otimes \mathbf{1}_q \ \mathbf{1}_p \otimes \mathbf{Z} \ \mathbf{U}]$, where $\otimes$ is the Kronecker product, $\mathbf{1}$ is a column of ones, $\mathbf{X}$ is the design matrix of the design array, $\mathbf{Z}$ is the design matrix for the noise array, and $\mathbf{U}$ is a model matrix with columns formed by element-by-element multiplication of the each of the k design factor columns in $\mathbf{X} \otimes \mathbf{1}_q$ with each of the m noise factor columns in $\mathbf{1}_p \otimes \mathbf{Z}$. If design-by-design factor or noise-by-noise factor interactions were supported by the experimental design, these could also be appended onto the $\mathbf{X}$ and $\mathbf{Z}$ matrices respectively. Least-squares estimates for the parameters are now obtained by $\hat{\boldsymbol{\theta}} = (\hat{\boldsymbol{\beta}}' \hat{\boldsymbol{\alpha}}' \hat{\boldsymbol{\lambda}}')' = (\mathbf{W}'\mathbf{W})^{-1} \mathbf{W}'\mathbf{y}$. All of these estimates could be inserted into the optimization problem in equation (6). However, many of these effects may not be significant in which case the problem can be substantially simplified.

A normal plot of all the effects from the robust design experiment, shown in Figure 4, shows that both noise factor main effects and the main effects of design factors x_1 , x_2 , and x_4 are significant. The only design-by-noise factor interactions that are significant

Figure 4 A normal plot of the effects for the crossed array

are the interactions between x_1 and z_1 and the interaction between x_2 and z_2 . In Table 4, values for the historical variances of the noise factors are given. After reducing the regression to include only the significant effects, the mean square error from the regression can be used as an estimate of σ^2 ; in this case $\hat{\sigma}^2 = 22.5$.

Using the values from Table 4 and the reduced model, the robust design problem becomes

$$\begin{aligned} \text{Minimize : } E(y) &\approx 79.24 - 3.18x_1 \\ &\quad - 8.53x_2 + 3.69x_4 \end{aligned}$$

$$\begin{aligned} \text{Subject to : } \text{Var}(y) &\approx (\hat{\alpha}_1 + \hat{\lambda}_{11}x_1)^2 \text{Var}(z_1) \\ &\quad + (\hat{\alpha}_2 + \hat{\lambda}_{22}x_2)^2 \text{Var}(z_2) + \hat{\sigma}^2 \\ &\approx (-5.88 + 6.84x_1)^2(6) \\ &\quad + (10.14 - 4.59x_2)^2(4) \\ &\quad + 22.5 \leq 100. \end{aligned} \quad (7)$$

If it is assumed that $E(z_i) = 0$ and that the design factors can only be set to values between -1 and 1 , then the following logic can be used to solve equation (7). If $x_1 = 0.86$, then the first term in the variance model is zero. The second term cannot be set to zero unless $x_2 > 1$, so to minimize variance and stay within the acceptable range, $x_2 = 1$, this leads

to $\text{Var}(y) \approx 145.71 \not\leq 100$. The mean surface roughness is reduced by setting $x_1 = x_2 = 1$ and $x_4 = -1$. Clearly, to reduce the variance below 100, one needs to explore the idea of further increasing x_2 , the knife temperature. However, if the constraints are observed, the robust design would be $x_1 = 0.86$, $x_2 = 1$, and $x_4 = -1$, alternatively, one could choose the settings, $x_1 = x_2 = 1$ and $x_4 = -1$ which would have a slightly lower mean but would have slightly higher variance. The trade-off between low mean and low variance should be made by the engineers knowledgeable about the consequences of surface roughness in the final application of the plastic beams. Again the conclusions here are relatively clear since this example was constructed for discussion purposes. However, if the models in equation (7) were more complicated, optimization techniques could again be used to solve the problem.

A simple, graphical method that can often be used to reduce the variance function involves making

Table 4 Historical variances for the noise variables in standard operating mode

Noise variable	Historical variance in operating mode
z_1	6
z_2	4

Figure 5 The interaction plot for knife temperature and percent recycled plastic

Figure 6 The interaction plot for knife speed and ambient temperature

and interpreting the design-by-noise factor interaction plots. In Figures 5 and 6, the interaction plots for the two significant design-by-noise interactions are shown. Figure 5 shows that the effect of changing ambient temperature, z_2 , from the low level to the high level is substantially smaller if the knife speed, x_2 , is set to its high level. It suggests that if $x_2 > 1$, the effect of ambient temperature might even be further reduced. Figure 6 suggests that the effect of percentage of recycled plastic may be close to zero if the knife temperature is set just below its high level. These are exactly the same conclusions that were made when equation (7) was solved. Thus for many cases, sophisticated optimization methods are not

necessary, simply looking at normal plot of effects and the interaction plots for the significant design-by-noise factor interactions may be sufficient to find the design factor settings that minimize the effects of the noise factors and thus give a robust design.

Experimental Design with Noise Factors

There are three primary considerations that are important when designing a robustness experiment that includes controllable noise factors. These are as follows:

1. Estimability of the design-by-noise factor interactions.
2. Restricted randomization (split-plot designs) (*see Randomization in Experimental Designs; Split-Plot Designs*).
3. Precision of the design-by-noise factor interaction estimators.

In standard experimental designs like fractional factorials, it is usually assumed that main effects are the most important effects, two-factor interaction effects are the next most important and so forth. Design criteria like resolution and minimum aberration (*see Minimum Aberration, Factorial Designs, Resolution of*, and [16]) were developed under this assumption and seek to keep the estimators of these important effects from being confounded together. However, as we have previously seen, estimation of the design-by-noise factor interactions is a primary goal of a robust design experiment. This means that design-by-noise factor interactions are more important than other two-factor interactions and maybe even as important as the main effects. This realization has led to a large literature on designs that allow for estimation of all design-by-noise factor interactions. It is well known that crossed arrays (where both design and noise arrays are at least resolution III) will never have design-by-noise factor interactions aliased (*see Aliasing in Fractional Designs*) with any main effects or any other two-factor interactions. Therefore, as Taguchi originally suggested, crossed arrays are good design for robust design experiments. However, Box and Jones [7] and Borkowski and Lucas [5] noted that there may be designs with fewer trials, often called *combined arrays*, that also protect the design-by-noise interactions from confounding. Wu and Hamada [35, pp. 484–492] provide a table of efficient robust design experiments that do not confound design-by-noise factor interactions with main effects or two-factor interactions.

The second major design consideration has to do with the order in which the trials in an experiment are run and how that affects the analysis of the data. Traditional analysis of experiments assumes that the trials in the experiment are run in a random order. However, in many (if not most) experiments, the order of the trials is determined by convenience. For example, observe the plastic beam experiment in Table 3, it is easy to imagine that all of the design factors can be changed from their low to high levels

in just a few minutes. The noise factors are different. When changing the ambient temperature, it might take an hour or two before all the equipment in the room actually reaches a steady-state temperature. Similarly, changing from a low percentage of recycled plastic to a high percentage or *vice versa* might require 15–20 min to allow all the plastic that is currently in the extruder to be replaced by the new blend. Thus, it would require much less time to run the 32 trials if the ambient temperature and the percent recycled plastic are both set to the low level and then all eight observations in the first column are taken (in random order). Next, one might increase the percentage of recycled plastic and then run all eight trials in the third column. Each of the other two columns of observations would then be taken in turn.

Experiments like this where certain factors are held constant for portions of the experiment are called *split-plot experiments* (*see Split-Plot Designs; [7, 3]*). Split-plot experiments require a somewhat more complicated analysis since some effect estimators have high variance and other effect estimators have lower variance. Specifically, the estimators of the effects of the factors that are run in a random order will have lower variance than the estimators of the effects of the factors that are held constant for large parts of the experiment. If the plastic beam experiment is run in the order suggested above, the noise factor effect estimators will have high variance since they are held constant while the entire column of observations is taken. The design factor effect estimators and the design-by-noise factor interactions will have lower variance. Thus, running this design in a convenient order has not only reduced the amount of time that it takes to run the experiment, but it also allows certain effects to be estimated more precisely. If the normal plot method of analysis is used, then the only difference in the analysis is that both the noise factor main effects and the noise-by-noise factor interaction should be removed from the normal plot since they are known to have higher variance than the other effects (*see [4]*).

In some situations, it may be the design factors that are held constant while all the noise factor settings across the row are run in a random order. In this case, it would be the design factor main effect estimators and all the design-by-design factor interactions that would have higher variance and would need to be removed from the normal plot of effects. If there are enough of these removed effects, they can be put on

a separate normal plot since all of these estimators have the same (higher) variance. Whether it is the design factors or noise factors that are held constant, it is clear that crossed arrays will often be run as split-plot experiments. However, several authors have shown that there often exist designs smaller than the corresponding crossed array that can also be run as split-plot designs. Bingham and Sitter [2, 3] provide tables of efficient split-plot designs and advice for their use and analysis.

Finally the last consideration for design of robustness experiments occurs when the experiment is being run as a split-plot experiment. The issue is whether the design-by-noise factor estimates have the higher or lower variance. Since the design-by-noise factor interactions are so important for finding a robust design, it would be best if the estimators for these effects had low variance. A crossed array, when run as a split-plot design (with either the design factor settings or the noise factors settings held constant), will always provide estimates of the design-by-noise factor interactions at the lower variance (see [7]). Other split-plot designs may also achieve this goal, but choosing a crossed array ensures this property.

In summary, crossed arrays, as originally suggested by Taguchi for robust experiments, have remarkably good properties for estimating design-by-noise factor interactions without confounding and with high precision when run as a split-plot design. Thus, when running a robust design experiment with controllable noise factors, a crossed array will be relatively easy to design and will have good design properties. However, by searching the literature for a more sophisticated design, one can often find a design that has fewer observations than the crossed array and many, if not all, of its good design properties.

BRUCE E. ANKENMAN

Signal–Response Systems

Introduction

A signal–response system is one where the function of the system requires a response variable to take different values as a result of changes in the signal factor. How well the system performs is determined by the characteristics of the relationship between the signal factor, M , and the response, Y . A number of different types of systems fall into this classification as illustrated by the following three examples.

Example 1: Alashe *et al.* [1] describe an experiment that investigated the engine idling performance of vehicles. Of particular interest was the relationship between the fuel flow (signal) and indicated mean effective pressure or IMEP (response). The IMEP is a measurement of the average pressure exerted on the piston during each power stroke and thus is related to the power generated by the engine. If the engine is efficiently converting fuel to power over the entire practical range of fuel flow then the relationship between fuel flow and IMEP should be approximately linear with an optimal slope that depends on the technical specifications of the engine. The goal of the experiment was to configure the engine so that the fuel flow/IMEP relationship was as close as possible to the optimal relationship.

Example 2: DeMates [2] describes an experiment conducted to improve the performance of an injection-molding machine. The machine was used for different applications that required different amounts of material to be delivered to the mold. It was necessary to be able to control the amount of material delivered by the machine and it was decided that this could best be done by adjusting the high injection pressure. Thus high injection pressure was designated as the signal factor and the amount (weight) of material delivered as the response. Ideally, the operator would be able to set the injection pressure so that exactly the desired amount of material was delivered for a wide range of target weights. Of course in practice there will always be some variability in the amount of material delivered. The goal of the experiment was to set the controllable aspects of the injection-molding machine so that the injection pressure could be used to control the amount of

material delivered with as little variability from the target values as possible.

Example 3: Most **measurement systems** fall into the signal–response classification. For example, atomic-absorption spectroscopy is a standard method of measuring the concentration of metal ions in liquid samples that is used for a wide range of metals. For a particular metal the atomic-absorption spectrometer focuses a beam of UV light through a flame and into a detector. The liquid sample is aspirated into the flame and if the metal is present the flame will absorb light of a wavelength specific to that metal. The amount of light absorbed increases as the concentration of metal in the sample increases. A **calibration curve** is created by measuring the rates of absorption for a set of standards which are solutions that contain known concentrations of the metal. The amount of metal in the sample is estimated by comparing the measured rate of absorption for the sample to the calibration curve. In this example, the concentration of metal in solution is the signal, the rate of absorption is the response and the calibration curve is the signal–response relationship. The characteristics of the calibration curve determine the precision of the estimated concentration of the metal in the sample.

This article starts by discussing how the performance of signal–response systems can be assessed (“Measuring the Performance of a Signal–Response System”), it then discusses approaches to designing and analyzing signal–response systems (“Robust Parameter Design for Signal–Response Systems”), a case study is presented to illustrate these approaches (“Case Study”), and it concludes by giving some selected references for further reading (“Concluding Remarks”).

Measuring the Performance of a Signal–Response System

In investigating a signal–response system, a fundamental issue is how to evaluate the performance of the system. The selection of a suitable measure of performance will depend on the function and possibly the specific features of the system being studied. To assist in this discussion we will consider a simple statistical model where during normal operation of the system the response is a random variable whose

2 Signal–Response Systems

mean and (possibly) variance are functions of the signal factor:

$$E(Y) = f(M) \text{ and } V(Y) = \sigma^2(M) \quad (1)$$

Consider the three examples of signal–response systems from the previous section.

In Example 1 there is a specified target function, say $f_T(M)$, for the signal–response relationship. Thus it is desirable to make the actual signal–response relationship as close as possible to $f_T(M)$ and to make $\sigma^2(M)$ as small as possible over the range of values required for M . A common approach in such situations is to use a quadratic loss function to penalize for departures from the target function – see McCaskey and Tsui [3]. Thus the performance measure becomes the mean square error $[f(M) - f_T(M)]^2 + \sigma^2(M)$, averaged over the desired range of M .

Example 2 can be described as a multiple-target system. For multiple-target systems the signal factor is used to adjust the system to accommodate different target values for the response. There is no specific target function as the shape of the signal–response relationship is not of direct concern but the signal–response relationship must allow the entire set of target values for the response to be achieved. The main objective is to reduce the variance in the response over the set of target values. Thus, an obvious choice is to use the variance, $\sigma^2(M)$, averaged over the set of desired target values with the caveat that the entire set can be achieved.

Example 3 is a measurement system. A measurement system uses the measured value of the response Y to predict the value of the signal M . The size of prediction error depends on the characteristics of the signal–response relationship and the goal is to find settings of the control factors that make these predictions as precise as possible. Miller and Wu [4] show that for a linear measurement system with constant variance – $Y = \beta_0 + \beta_1 M + \epsilon$, $\epsilon \sim N(0, \sigma^2)$ – the expected size of the Fieller’s interval is a monotonically decreasing function of β_1^2/σ^2 . That is, as β_1^2/σ^2 increases the estimates become more precise. Thus, β_1^2/σ^2 is an obvious choice for the performance measure. Although having a linear signal–response relationship and constant variance simplifies the calibration problem, these are not essential for measurement systems. More generally, one could base a performance measure on the “criterion for technical

merit” for measurement systems devised by Mandel [5]: $(f'(M))^2/\sigma^2(M)$. For example, the average of this quantity over the desired range for the signal factor could be used.

Robust Parameter Design for Signal–Response Systems

The investigation of signal–response systems through designed experiments was originally discussed by Taguchi [6] as a special case of robust parameter design (*see Robust Design*). Taguchi identified two types of applications which he called *static* problems and *dynamic* problems. The difference can be illustrated using Example 2 which, as described, is what Taguchi would classify as a dynamic characteristic. However, if the injection-molding machine was only used to produce a single part and the goal was to reduce variation around the target weight then it would be a static characteristic. Miller and Wu [4] used the term *signal–response systems* instead of dynamic characteristics as they felt this was a more appropriate description. In simple terms, the objectives of a **robust design** experiment applied to a signal–response system are to optimize the relationship between the expected response and the signal factor while minimizing the variability in the observed response. Typically, a set of control factors (factors whose levels can be set by the operator) is identified and an experiment is conducted to find the best settings for these factors. Usually the impact that the control factors have on the relationship between the expected response and the signal factor can be assessed with greater precision than their impact on variability. Thus it can be very advantageous to include noise factors in the experiment. Noise factors (*see Factorial Experiments*) represent suspected sources of variability in the response. They are factors that vary during the normal operation of the system but can be set at fixed levels for the purposes of an experiment. By identifying such factors and deliberately varying their levels in an experiment, the chances of identifying settings for the control factors that reduce the impact of these (noise) factors is greatly enhanced.

Two distinct approaches for conducting parameter design experiments have emerged. The first approach defines a specific criterion to be used to evaluate the performance of the system and then an experiment

is conducted with the goal of modeling this criterion as a function of the control factors. This model is used to determine the best settings for the control factors. This is the approach proposed by Taguchi who referred to the performance criteria as (*dynamic*) *signal-to-noise ratios* (see **Signal-to-Noise Ratios for Robust Design**). Conceptually, the experiment is the marriage of two parts. First, there is a primary experiment where the chosen criterion is the response and the levels of the control factors are varied according to a selected design usually referred to as the *inner array*. For each run in the inner array, a secondary experiment is run where the levels of the signal and noise factors are varied according to an “outer array” – the idea is that the outer array runs should encompass the range of conditions that the system is expected to experience. The overall design matrix for the experiment is created by combining each run in the inner array with every run in the outer array (see **Product Array Designs**). The analysis uses a two-stage procedure. The first stage is to estimate the criterion for each run (combination of control factors) in the inner array using the set of observations taken by varying the signal and noise factors according to the outer array. The second stage treats these estimates as the observed response for the inner-array experiment and uses standard statistical techniques to assess the impact of the control factors on the criterion. Clearly, this approach can be applied to criteria other than Taguchi’s signal-to-noise ratios. Miller and Wu [4] use the term *performance measure modeling* to describe the general approach of modeling a chosen performance criterion directly as a function of the control factors.

The second approach is to model the response variable as a function of all of the factors (control, noise, and signal). This fitted model is used to determine the settings of the control factors that will optimize the performance of the system. Often this can be done without identifying a specific performance measure but, if necessary, a criterion can be chosen and the fitted response model can be used to evaluate it for different settings of the control factors. In designing an experiment for this approach, a single design array can be used to set the levels of all of the experimental factors (control, noise, and signal). For reasons of economy the experimenter may wish to use a **fractional factorial** design and having a single design array provides more flexibility in selecting such a design. Note that the fitted model is to be used

to assess how the control and noise factors affect the signal–response relationship and to find settings of the control factors that reduce the effect of the noise factors. As a result, it is important that the design allows signal $\times$ control, signal $\times$ noise, control $\times$ noise, and signal $\times$ control $\times$ noise interactions to be estimated in addition to main effects.

Miller and Wu [4] proposed a modification of the response modeling approach, which they named *response function modeling*. The key idea is to treat the signal–response relationship as the response and to model this relationship as a function of the control and noise factors. An experiment designed for this strategy, should use a single array to vary the control and noise factors and then for each run in that array vary the signal factor over a selected set of levels. The analysis employs a two-stage procedure. For each run in the control/noise array a parametric model is fitted for the signal–response relationship using the set of observations obtained by varying the signal factor. Thus, for each run a set of estimated parameters is obtained. The second stage uses standard techniques to investigate how the control and noise factors affect these parameters. For example suppose that the signal–response relationship is linear and has constant variance. For each run in the control/noise array a linear model of the form $Y = \beta_0 + \beta_1 M + \epsilon$ where $\epsilon \sim N(0, \sigma^2)$ would be fitted and estimates of β_0 , β_1 , and σ^2 obtained. Then the effects of the control and noise factors on each of β_0 , β_1 , and σ^2 would be assessed.

Case Study

The experiment used to investigate the injection-molding system described in the introduction (Example 2) will be used to illustrate the performance measure modeling and the response function modeling approaches. This article will just summarize these analyses – the interested reader is referred to Miller and Wu [4] for a more detailed description. One of the key objectives of this experiment was described by DeMates [2] as “. . . to identify the control factors and optimum settings that would reduce part weight variation over a range of molded part weights”.

Recall that for this example, high injection pressure was designated as the signal factor and the amount (weight) of material delivered to the mold used as the response. Eight levels were used for

4 Signal–Response Systems

Table 1 Control and noise factors for injection-molding case study

Control factor	Levels		Compound noise factor	Levels	
	+1	−1		+1	−1
A: Injection speed	2	0	Melt index	22	18
B: Clamp time (s)	44	49	Percent regrind (%)	0	5
C: High injection time (s)	6.3	6.8	Operator	Experienced	New
D: Low injection time (s)	17	20	Resin moisture	Low	High
E: Clamp pressure (psi)	1900	1700	Day	First	Second
F: Water cooling (F)	70	80			
G: Low injection pressure (psi)	650	550			

the signal factor which corresponded to varying the high injection pressure from 650 to 1000 psi in increments of 50 psi. A preliminary study indicated that the signal–response relationship could be adequately approximated by a quadratic polynomial with constant variance. The experiment investigated seven two-level control factors that represented modifications to the injection-molding system. These factors and the levels used are listed in Table 1. It was thought the system could also be affected by changes in raw materials, operators and environmental conditions. A single two-level compound noise factor (which involved setting the levels of five individual factors) was used to introduce variation from all three of these sources – the factors included in the compound noise factor are also listed in Table 1.

As this experiment was designed with a performance measure modeling approach in mind, an inner array was used to vary the control factors and an outer array was used to set the signal and noise factors. A 2^{7-4} fractional factorial design was used for the inner array and a full factorial (8×2) design was used for the outer array.

The experiment was run over 2 days where the compound noise factor was set to its low level on the first day and to its high level on the second day. On each day all combinations of the control factors in the inner array were tested. For each combination, the signal factor was varied over eight levels and four observations were taken at each level. From the description in DeMates [2] it appears that these four replicates were taken one after another without resetting the signal level between. Thus the variability between replicates should reflect the part-to-part variability in the process. Arguably, it may have been better to spread out replicates over time so that longer-term variation would have also been captured.

Performance Measure Modeling Analysis

The first step is to identify a suitable performance measure. If the primary goal is to reduce variability in part weight for a specific set of target weights then the obvious choice is the variance of part weights with the caveat that the full range of target values must be attainable.

Thus, for each run in the inner array, the variance is estimated using the set of observations obtained by varying the signal and noise factors over the outer array. Notice that there are 64 runs in each set: 32 on day 1 ($N = -1$), which consist of four replicates at eight levels of the signal factor and a similar set of 32 on day 2 ($N = +1$). For each inner-array run a quadratic regression model,

$$Y = \beta_0 + \beta_1 M + \beta_2 M^2 + \epsilon$$

where

$$\epsilon \sim N(0, \sigma^2) \quad (2)$$

is fitted and $\hat{\sigma}^2$ is used as the estimated performance measure – see Table 2. These values are treated as the response for the eight-run control factor design. In actual fact, $\log(\hat{\sigma}^2)$ is analyzed because it better meets the regression model assumptions. The estimated effects for the seven factors are 1.07 (A), 0.67 (B), −0.39 (C), −0.64 (D), 0.14 (E), −0.19 (F), and −0.16 (G). A **half-normal plot** (not given) of these effects indicates that factor A and possibly factors B and D warrant further consideration. From the signs of the effects the settings $A = -1$, $B = -1$, and $D = +1$ are recommended to minimize σ^2 . Finally, it would need to be confirmed that entire set of target weights can be attained for this combination of factor settings.

Table 2 Inner and outer arrays for performance measure modeling analysis

Run	Control factors							$\hat{\sigma}^2$	Run	M	N
	A	B	C	D	E	F	G				
1	1	1	1	1	1	1	1	8.39	1	600	-1
2	1	1	1	-1	-1	-1	-1	19.70	2	650	-1

Response Function Modeling Analysis

For this approach a fitted model of the signal-response relationship is obtained for each combination of the control and signal factors (16 in total). Orthogonal polynomials will be used in the quadratic model as to simplify the interpretation of the results. The model can be written as follows:

$$E(Y) = \beta_0 + \beta_1 P_1(M) + \beta_2 P_2(M) + \epsilon, \epsilon \sim N(0, \sigma^2) \quad (3)$$

where the values $P_1(M)$ and $P_2(M)$ are given in Table 3. For this model, β_0 is the mean of Y , β_1 is the linear component of the signal-response relationship, and β_2 is the quadratic departure from linearity. In this case σ^2 represents the part-to-part variability in the process observed when the control and noise factors are fixed. For each of the 16 runs in the combined array estimates are obtained for β_0 , β_1 , β_2 , and σ^2 . For this example, Miller and Wu [4] argued that just the pure error estimate of σ^2 (the estimate based on replicate observations) should be used since residual plots revealed some unusual patterns that indicated an estimate based on **lack of fit** may not be reliable. Table 4 contains the estimated parameters for each run in the control/noise array ($\hat{\sigma}_p^2$ is the pure error estimate of σ^2).

Table 3 Levels for orthogonal polynomials

	Signal factor levels							
	650	700	750	800	850	900	950	1000
$P1(M)$	-7	-5	-3	-1	1	3	5	7
$P2(M)$	7	1	-3	-5	-5	-3	1	7

Each of the estimated parameters is modeled as a function of the control and noise factors. A total of 15 effects are calculated corresponding to the main effects of the control and noise factors and the seven control $\times$ noise two-factor interactions. Half-normal plots were used to evaluate which effects should be included in the models for the parameters – the half-normal plots and model selection details are omitted here but can be found in Miller and Wu [4]. The fitted models for the parameters are

$$\begin{aligned} \beta_0 &= 666.4 + 1.2A - 1.8C + 1.4E - 1.0F \\ &\quad + 1.8G + 1.1N \\ \beta_1 &= 4.79 + 0.16C \\ \beta_2 &= 1.33 + 0.03B - 0.04D - 0.05E - 0.04N \\ &\quad + 0.01A \times N - 0.03F \times N - 0.02G \times N \\ \log(\sigma_p^2) &= 0.12 + 1.10A + 0.22B - 0.21C \\ &\quad + 0.40N + 0.28E \times N + 0.04E \end{aligned} \quad (4)$$

Variability in the response can be decreased in two ways: (a) decrease the impact of the noise factor on the signal-response relationship and (b) decrease the part-to-part variability. First consider decreasing the impact of the noise factor. The fitted models indicate that N affects β_0 and β_2 but not β_1 . The model for β_0 indicates that the signal-response curve is shifted up when N is at the +1 level relative to -1 level. As no control $\times$ noise interaction shows up in this model, no method of reducing this shift has been found. The model for β_2 indicates that the signal-response relationship exhibits more curvature when N is at the -1 level than at the +1 level. As the model also includes terms for the $A \times N$, $F \times N$, and $G \times N$

Table 4 Control/noise array for response function modeling analysis

Run	Control and noise factors								Parameters			
	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>	<i>E</i>	<i>F</i>	<i>G</i>	<i>N</i>	$\hat{\beta}_0$	$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\sigma}_p^2$

16	−1	−1	1	−1	1	1	−1	−1	663.6	5.02	1.29	0.12

interactions, it should be possible to reduce the impact of N by judiciously selecting levels for A , F , and G . Now consider using the $\log(\sigma_p^2)$ model to reduce part-to-part variability. This model clearly indicates that A has the biggest impact and should be set to the -1 level and that factor B should be set to the $+1$ level and C to the -1 level. The model also includes terms for the compound noise factor N and the $E \times N$ interaction. It indicates that part-to-part variation is higher for N at the $+1$ than the -1 level. Setting E to -1 will make part-to-part variation more consistent across levels of N (it does this by decreasing the variance for the $+1$ level but increasing the variance for the -1 level).

Notice that the response function modeling approach has given a much clearer picture of how the control factors affect the nature of the signal–response relationship and the impact of the compound noise factor than the performance measure modeling procedure did. Performance measure modeling only provides an overall assessment of how control factors affect the performance of the system. No information is gained on how specific control factors affect the shape of the signal–response relationship or interact with noise factors. This type of information can be very valuable in suggesting directions for future research.

Concluding Remarks

There is considerable diversity of opinion with regards to methodology that should be used to analyze experiments involving signal–response systems. General discussions of signal–response systems including detailed treatments of both the performance measure modeling and the response function modeling approaches can be found in Miller and Wu [4] and Wu and Hamada [7]. Taguchi’s signal-to-noise ratio approach is still very popular and there are numerous books available that explain this methodology. Two examples are Taguchi *et al.* [8] and Wu and Wu [9]. Lunani *et al.* [10] suggest a method of generalizing Taguchi’s dynamic signal-to-noise ratio approach to make it more flexible. Tsui [11, 12] discusses and develops the response modeling approach. Joseph and Wu [13] propose a methodology that extends Taguchi’s signal-to-noise ratio approach and a methodology that extends response modeling. Miller [14] discusses the response function modeling approach and suggests some additional refinements. Nair *et al.* [15] adapt some functional response techniques to the analysis of signal–response systems. Their approach is similar to response function modeling in that the signal–response relationship is treated as the response but it allows systems to be investigated where no simple parametric model that describes the

signal-response relationship can be identified. Lesperance and Park [16] propose using joint **generalized linear models** for the analysis of signal-response systems adapting the procedure proposed by Nelder and Lee [17].

Signal-to-Noise Ratios for Robust Design

Taguchi's Parameter Design for a Fixed Target

Robust design (RD; *see* **Robust Design**) is a systematic methodology that applies statistical experimental design to improve the design of products and processes. By making product and process performance insensitive (robust) to hard-to-control disturbances (noise), RD simultaneously improves product quality, the manufacturing process, and reliability. The original RD method developed by the Japanese quality consultant, Genichi Taguchi ([1]; is called *parameter design*. Taguchi's 1980 introduction of robust parameter design to several major American industries resulted in significant quality improvements in product and process design (see [2]). Since then, a great deal of research on RD has improved related statistical techniques and clarified underlying principles. Representative examples include Shoemaker *et al.* [3] and Tsui [4, 5].

The most widely applied of Taguchi's robust parameter design methods is static RD, in which the process response has a single, unchanging target value. All of Taguchi's robust parameter design methods assume the response is affected by easily manipulated variables, that is, control factors, as well as hard-to-control variables, that is, noise factors. The aim of static RD is to choose a vector of control variable settings that simultaneously reduces the variability of the process response and sets the response to the desired target value.

The key ideas behind static RD are nicely illustrated by a tile manufacturing example described in Taguchi and Wu [1] and Phadke [6]. The Ina Tile Company was experiencing large variation in its tile dimensions, resulting in unwanted scrap and expense. The engineers first determined that the variability in the response of interest, that is, tile dimensions, was caused by uneven heating of the tiles in the kiln. Tiles in the center of the stack in the kiln were heated to a lesser degree than those placed on the outside of the stack, hence causing the variation in dimension. A redesign of the kiln would solve the problem, but it would be an expensive solution.

Instead, the engineers identified several process factors that could be varied inexpensively. They performed carefully planned experiments to determine which combination of process factors would make tile dimensions robust against the uneven distribution of heat within the kiln. The engineers found that by increasing the lime content of the clay from 1 to 5%, the variability in tile dimensions would be greatly decreased.

The engineers discovered that an easily adjusted control variable, that is, lime content, made tile dimensions robust against a difficult to adjust noise factor, namely the uneven distribution of heat within the kiln. Adjusting the lime content allowed the tile dimensions to meet target specifications with reduced variation.

As the Ina Tile example shows, the goal in parameter design is to improve quality by achieving a desired target level coincident with low variability. More formally, the objective is to minimize the quadratic loss function popularized by Taguchi,

$$L(Y, t) = k(Y - t)^2 \quad (1)$$

where Y is the value of the process response, t the desired target value for Y , and k is a constant called the *quality loss coefficient*, equal to A_0/Δ_0^2 in which Δ_0 is the customer's tolerance around target t , and A_0 represents the loss in dollars or other units when the tolerance Δ_0 is exceeded. The average or expected loss may be decomposed as follows:

$$\begin{aligned} R(\mathbf{C}) &= kE_{\mathbf{N},\epsilon}(Y - t)^2 \\ &= k[\text{Var}_{\mathbf{N},\epsilon}(Y) + (E_{\mathbf{N},\epsilon}(Y) - t)^2] \end{aligned} \quad (2)$$

where $\mathbf{C}$ is a vector of design variables that can be partitioned into two mutually exclusive parts corresponding to "nonadjustment" factors, which do not affect the response mean, that is, $\mathbf{d} = (d_1, \dots, d_p)$, and "adjustment" factors, which can be used to adjust the response mean to the target, that is, $\mathbf{a} = (a_1, \dots, a_q)$. The goal is to find the factor settings in $\mathbf{d}$ and $\mathbf{a}$ that will minimize $R(\mathbf{C})$. Note that this partitioning of design variables is a theoretical ideal, and mutually exclusive groupings may not exist in practice. $\text{Var}_{\mathbf{N},\epsilon}(Y)$ and $E_{\mathbf{N},\epsilon}(Y)$ are the mean and variance of the process response over the random sources of variability represented by $\mathbf{N}$ and ϵ . $\mathbf{N}$ is a vector of uncontrollable "noise variables" (*see* **Factorial Experiments**) and ϵ represents purely random

variation. This decomposition of average quadratic loss allows us to frame RD as the minimization of the sum of process variance and the square of the deviation of process mean from the target.

Taguchi [7] introduced a family of performance measures called *signal-to-noise ratios* (SNRs) whose specific form depends on the desired response outcome. Instead of directly minimizing quadratic loss, Taguchi uses these SNR in his optimization procedure. Here we present three of the most common SNR for the static, or fixed target, problem that was illustrated previously with the Ina Tile example. The case where the response has a fixed nonzero target is called the *nominal-the-best* (NTB) case. Likewise the cases where the response has a unique smaller-the-better target or larger-the-better target are respectively called the *STB* and *LTB* cases. For these three cases Taguchi defined the SNR as follows:

$$SNR_i = \begin{cases} 10 \log_{10} \left[\frac{\bar{Y}_i^2}{S_{Y_i}^2} \right] & \text{for the NTB case} \\ -10 \log_{10} \left[\frac{1}{n} \sum_{j=1}^n Y_{ij}^2 \right] & \text{for the STB case} \\ -10 \log_{10} \left[\frac{1}{n} \sum_{j=1}^n \left(\frac{1}{Y_{ij}} \right)^2 \right] & \text{for the LTB case} \end{cases} \quad (3)$$

where SNR_i is the SNR for the i th combination of design factor settings in the experiment, $\bar{Y}_i$ and $S_{Y_i}^2$ are respectively the sample mean and variance of the response estimated from the n observations, that is, $Y_{i1}, \dots, Y_{in}$, at the i th design factor setting in the experiment.

To accomplish the objective of minimal expected squared-error loss for the NTB case, Taguchi proposes the following two-step optimization procedure:

1. Calculate and model the SNRs and find the values of the nonadjustment factor settings, that is, $\mathbf{d}$, which maximize the SNR.
2. Shift mean response to the target by changing the values of the adjustment factor(s) $\mathbf{a}$.

For the STB and LTB cases, Taguchi recommends directly searching for the values of the design vector

$\mathbf{C}$ which maximize the respective SNR. Alternatives to Taguchi's optimization approaches for these cases are proposed by Nair and Pregibon [8], León *et al.* [9], Box [10], and Tsui and Li [11].

Taguchi's Parameter Design for Multiple Targets

The term *dynamic robust design* (DRD), also known as a *signal-response system* (see **Signal-Response Systems**), signifies that there are multiple targets of interest for the process response. In static RD there is a single, fixed target value and the variables affecting process response are considered as either design or noise variables. In DRD there exists a third type of variable, the signal variable M , whose magnitude directly affects the mean value, and thus the target, of the output response.

Consider, for example, a push-pull cable actuator system which consists of a flexible release cable assembly, similar to one used for an automobile's remote mirror adjuster, or hood and trunk releases. This example was examined in McCaskey and Tsui [12] and Byrne and Quinlan [13]. The response of interest is output displacement measured in millimeters, which is affected by control and noise factors, as in the static case. In addition however, the cable system is affected by a user-influenced signal variable M , the input displacement, which affects the target value of the output response.

Note that for the static case of Ina Tile the targets of the tile dimensions were always fixed at specific values. A mirror adjuster moves the mirror to different positions based on the drivers' needs. These different mirror locations desired by the driver represent different target values to be achieved by adjustment of the control variables while maintaining low variability in response.

In order to optimize the design of a cable actuator, a study was planned in which 11 control factors (labeled $A-K$) were varied at two levels each using an OA12 orthogonal array (see **Orthogonal Arrays**). This 12-run, highly fractionated Taguchi design is comparable to the $N = 12$ Plackett-Burman design (see **Plackett-Burman Designs**), in which each two-factor interaction is partially aliased with nine main effects. This design is useful for efficiently screening a large number of variables when two-factor interactions are not anticipated.

The 11 control factors varied in the study included liner material modulus, braid wire diameter, liner wall thickness, braid density, coating material modulus, coating thickness, cable diameter, and cable material modulus. In addition to the OA12 inner array, two combinations of noise factors and three settings of the signal variable were incorporated into the outer array of the design. The signal variable settings corresponded to the specific mirror locations drivers were likely to use most. The noise factors were manufacturing characteristics that are very difficult to control, specifically number of cycles, assembly length, routing, and operating load. Three experimental replicates for each combination of control, noise, and signal settings were performed, resulting in 216 ($12 \times 2 \times 3 \times 3$) total observations. The experimental design and data are listed in Table 1. Note that the data in this presentation has been modified from the original experimental results found in McCaskey and Tsui [12] and Byrne and Quinlan [13] to more clearly illustrate Taguchi's optimization procedure for the DRD situation.

In analyzing the cable actuator data, we can begin

by specifying the loss function. A common choice of dynamic loss function is the quadratic loss function popularized by Taguchi,

$$L(Y, t(M)) = k(Y - t(M))^2 \quad (4)$$

where k is the constant described in equation (1) and $t(M)$ indicates that the target level is a function of the signal variable M . This loss function provides a good approximation to many realistic loss functions. It follows that the average loss becomes

$$\begin{aligned} R(C) &= kE_M E_{N,\epsilon}(Y - t(M))^2 \\ &= kE_M [\text{Var}_{N,\epsilon}(Y) + (E_{N,\epsilon}(Y) - t(M))^2] \end{aligned} \quad (5)$$

where E_M is the expected value over the range of the user-influenced signal variable M and N and ϵ are sources of variability contributed by the uncontrollable noise variables and pure random error.

The SNR for the cable actuator study must also incorporate the effect of the signal variable. Taguchi

4 Signal-to-Noise Ratios for Robust Design

suggested the following SNR as a performance measure for the dynamic case:

$$SNR_i = 10 \log_{10} \frac{\hat{\beta}_i^2}{S_i^2} \quad (6)$$

where $\hat{\beta}_i$ is the regression coefficient from fitting the responses Y_{ij} to the signal M , that is,

$$\hat{Y}_{ij} = \hat{\beta}_i M \quad (7)$$

where β_i can be interpreted as the slope of the linear model between Y_{ij} and M with a zero intercept for the i th design factor setting and S_i^2 is the sample error variance of the i th fitted regression model. As in the static case, Taguchi recommends a two-step optimization procedure:

1. Calculate and model the SNR of equation (6) and find the nonadjustment factor settings, that is, $\mathbf{d}$, which maximize it.
2. Shift the mean slope $\hat{\beta}$ to the desired sensitivity level using the adjustment factor(s) $\mathbf{a}$.

Alternatives to Taguchi's performance measures and optimization procedures for DRD are proposed in Tsui [14] and Joseph and Wu [15, 16].

The upper half of Table 2 shows SNR responses for each level of the 11 control factors. From visual inspection of these results and consultation with the engineers designing the cable actuator system, control factors B and D , respectively corresponding to braid wire diameter and braid density, were chosen as the set of nonadjustment factors $\mathbf{d}$.

Next, a separate analysis was performed to determine the adjustment factors $\mathbf{a}$ that affect the signal-response slope. For this example the engineers desired a 1:1 relationship between the input

displacement signal and the output displacement response, corresponding to a slope of 1. Taguchi suggests calculating an SNR for the estimated slopes, $SNR_{\beta i}$:

$$SNR_{\beta i} = 10 \log_{10} \hat{\beta}_i^2 \quad (8)$$

The $SNR_{\beta i}$ responses for each level of the 11 control factors are shown in the lower half of Table 2. We see that factor H , that is, the cable material modulus, can be used to adjust the slope to its theoretically ideal value which in this case is 1. The design engineers verified that this was a reasonable choice to use as an adjustment variable.

Using the information in Table 2 to apply Taguchi's two-step optimization procedure we have the following conclusions:

1. Set the factors B and D to levels $B = 1$, $D = 1$ to maximize the SNR.
2. Assuming that it can be adjusted over a sufficiently wide range, use factor H to adjust the signal-response slope to its theoretically ideal value.

The factor settings determined from the two-step procedure will then, according to Taguchi, minimize the expected quadratic loss for the dynamic problem.

Strengths and Limitations of Taguchi's SNR

The concept of the SNR originated in electrical engineering to quantify a circuit's ability to discern a meaningful signal from the wide frequency spectrum of which it is a single component. The concept of comparing the strength of a signal to its companion noise is best demonstrated by the NTB case of

Table 2 SNR and SNR_{β} responses by control factor levels for the cable actuator experiment – simulated data

Factor	A	B	C	D	E	F	G	H	I	J	K
SNR											
Level 1	0.83	3.80	0.66	1.74	0.75	0.16	0.71	0.26	0.68	0.65	0.69
Level 2	0.06	−2.91	0.22	−0.85	0.14	0.72	−0.18	0.63	0.21	0.24	0.20
Difference	0.77	6.71	0.44	2.59	0.60	0.56	0.53	0.37	0.47	0.41	0.49
SNR_{β}											
Level 1	−4.70	−4.86	−4.79	−4.50	−4.57	−5.05	−4.75	−6.05	−4.76	−4.73	−4.79
Level 2	−4.94	−4.77	−4.85	−5.13	−5.06	−4.58	−4.88	−3.58	−4.87	−4.91	−4.85
Difference	0.24	0.09	0.06	0.63	0.50	0.47	0.13	2.47	0.11	0.18	0.06

equation (3) which is the logarithm of the ratio of the sample response mean (i.e., signal) squared to the sample response variance (i.e., noise). The SNR is the most controversial part of Taguchi's methods because it summarizes the quality information from the entire experiment with a single performance measure. Other methods examine separate measures of location and dispersion or transformations thereof.

In RD, the performance measure tells how a process is functioning. The advantages of the SNR advocated by Taguchi are twofold. Foremost, it has great appeal to an audience who are not statistically sophisticated as a single measure that encompasses all experimental information. Secondly, when combined with the simplicity of the two-step procedure, it has functioned as a powerful incentive for engineers and scientists to employ designed experiments to improve the quality of their products. Bridging the worlds of engineering and applied statistics is generally acknowledged as Taguchi's greatest contribution.

Conversely the statistical community has been troubled by the unexplained connection between maximizing the SNR and achieving the stated goal of minimal quadratic loss. Recall that the two-step procedure consisted of maximizing the SNR and then using adjustment factors which have negligible effect on the SNR to bring the process mean to target. Taguchi did not rigorously prescribe how this procedure guaranteed minimal quadratic loss.

The relationship between minimization of expected quadratic loss and Taguchi's SNR was articulated by León *et al.* [9]. They defined a function called the *performance measure independent of adjustment* (PerMIA; see **Performance Measures for Robust Design**) which justified the use of a two-step optimization procedure. They showed that Taguchi's SNR for the NTB case is a PerMIA when an adjustment factor exists and σ_Y^2 is proportional to μ_Y . When Taguchi's SNR complies with the properties of a PerMIA, his two-step procedure minimizes the expected value of squared-error loss.

León *et al.* [9] also emphasized two major advantages of Taguchi's two-step procedure:

- it reduces the dimension of the original optimization problem;
- it does not require reoptimization of the nonadjustment factors (**d**) for future changes of the target value. The adjustment factors (**a**) can be used to accommodate future changes in target.

Since the work of León *et al.* [9] the SNR has been extensively reviewed by the statistical community. Box [10] recommends modeling the process response Y with appropriate transformation as needed to find design factor settings that minimize **mean squared error**. He points out that even when σ_Y^2 is proportional to μ_Y , the analysis of $\log(Y)$ is more efficient than the SNR. A more recent comparison of the SNR with alternative performance measures is presented in Bérubé and Wu [17], and Wu and Hamada [18] provide a variety of approaches for related situations.

An important paper that compared use of Taguchi's SNR to process response was that of Nair and Pregibon [8] who advocate a three-phase process for RD consisting of exploration, modeling, and optimization. Their performance measure is process response which they assume is a function of the design and noise variables, that is, **C** and **N** referred to in equation (2). They reduce the RD problem to minimization of VAR_Y subject to the constraint that E_Y is held as close as possible to the target level t .

Other excellent discussions of the SNR and Taguchi's related parameter design techniques include Kackar [19], Nair [20], and Tsui [21]. In the last 10 years most research on RD has focused on DRD with seminal work including that of Miller and Wu [22], Lunani *et al.* [23], and McCaskey and Tsui [12]. More recent contributions include those of Joseph and Wu [15, 16].

Tolerance Design

Introduction

The three main stages in a product/process design are system design, parameter design, and tolerance design [1]. In system design the basic architecture of the system is selected; in parameter design the nominal values of the parameters in the system are selected; and in tolerance design the allowable variations of the parameters around their nominal values are selected. This chapter discusses tolerance design. Tightening the tolerances increases the manufacturing cost, whereas widening the tolerances decreases the quality. Thus designing tolerances is about balancing cost with quality.

The quality of a product is measured with respect to customer requirements. Thus tolerance design activities begin with acquiring customer specifications and translating them to product specifications. A product may be an assembly of several components and each component may have several parameters. The objective in product design is to find the specifications of each parameter so that the desired product quality can be achieved. Each component itself may be manufactured in several stages of a manufacturing process and each stage may contain several parameters. Therefore the objective in process design is to find the specifications of each process parameter so that the component specifications can be achieved. In this chapter we discuss only the designing component and the process parameter tolerances and not the conversion of customer tolerances into product tolerances.

Let y be the output quality characteristic and $x_1, x_2, \dots, x_p$ be the input parameters (or factors). In reality, the input parameters are not constants and have variations around their nominal values. For example, product/component parameters vary because of the manufacturing variations; similarly manufacturing process parameters vary because they cannot be controlled precisely over time. Assume that (maybe after a suitable transformation) x_i follows a **normal distribution** with mean μ_i and variance σ_i^2 . We can write $x_i = \mu_i + \delta_i$, where $\delta_i \sim \mathcal{N}(0, \sigma_i^2)$. For some parameters, the designer can choose a value for μ_i , in which case δ_i is called an *internal noise* factor. If the designer has no control over the nominal value, then x_i is called an *external noise* factor.

Let the input–output relationship be $y = f(x_1, \dots, x_p)$. Because the x 's vary, y also varies. The variations in y can be large and not acceptable. One approach to reduce the variations in y is to reduce the variations in the x 's. This can be done by tightening the tolerances, but it inadvertently increases the manufacturing cost. A more cost-effective approach is to use robust parameter design (*see Robust Design*). Here, the nominal values of the x 's are chosen such that the variations of y are as small as possible. Note that in robust parameter design, no effort is made to reduce the variability of the x 's, thus it does not increase the cost of manufacturing. However, even after the application of robust parameter design, the variations can still be large and tightening the tolerances becomes inevitable. But this clearly shows that tolerance design should be performed only after parameter design, not the other way. We will explain this using a simple example.

Example

Consider an example discussed in [2] on the design of a cyclone (see also [3]). A cyclone is used for separating solid mass and gaseous mass. The characteristic of output quality, the critical parameter of particles y , is related to seven input parameters by

$$y = 174.42 \left(\frac{x_1}{x_5} \right) \left(\frac{x_3}{x_2 - x_1} \right)^{0.85} \times \left(\frac{1 - 2.62[1 - 0.36(x_4/x_2)^{-0.56}]^{3/2}(x_4/x_2)^{1.16}}{x_6 x_7} \right)^{1/2} \quad (1)$$

The existing nominal values of the factors and their tolerances are given in Table 1. Here the tolerances are expressed as a percentage of the nominal values. For example, the specification of x_6 is 16 ± 4 . The objective is to find the optimal nominal values and tolerances such that the quality is maximized while minimizing the manufacturing cost.

The quality can be measured using a quality loss function [1] (see also [4]). In this example, the response is a nominal-the-best type characteristic and thus the following quadratic loss function can be used

$$L(y) = k(y - \tau)^2 \quad (2)$$

where τ is the target for the characteristic and k is a cost coefficient. Here $\tau = 1.5\text{ m}$ and $k =$

2 Tolerance Design

Table 1 Existing values of the factors and tolerances

Factors	x_1	x_2	x_3	x_4	x_5	x_6	x_7
Nominal values	0.10 m	0.30 m	0.10 m	0.10 m	1.50	16.00 m s ⁻¹	0.75 m
Tolerances (%)	25	25	25	25	25	25	25

$1/9 \times 10^5$ yen m⁻². The determination of k is not trivial, see [2, 3] for details. Although an accurate **estimation** of k is not important for parameter design, it is important for the tolerance design. The average quality loss can be obtained as

$$Q = E[L(Y)] = kE[f(\mu_1 + \delta_1, \dots, \mu_p + \delta_p) - \tau]^2 \quad (3)$$

where the expectation is taken with respect to the distribution of the noise factors.

To evaluate the quality loss, we need to know the distribution of the noise factors. Because no information is available about σ_i in the cyclone design example, we will indirectly estimate it by assuming that the tolerance is equal to three times the standard deviation. Let t_i denote the tolerance of factor i . Thus, assume that $\sigma_i = t_i/3$. In general, it is difficult to find a closed-form expression for Q . One simple method to estimate Q is to use a **Monte Carlo** approximation. Generate n independent samples for each δ_i from $\mathcal{N}(0, \sigma_i^2)$. Then

$$\hat{Q} = \frac{k}{n} \sum_{j=1}^n [f(\mu_1 + \delta_{1j}, \dots, \mu_p + \delta_{pj}) - \tau]^2 \quad (4)$$

Using $n = 10\,000$, we obtain $Q = ¥2096$ per product for the existing design.

In the robust parameter design, the nominal values of the control factors are chosen to minimize the sensitivity of the response to the noise factors. This can be achieved by minimizing the average quality loss with respect to $\mu_1, \dots, \mu_p$. Because there is no explicit expression for Q in terms of μ_i 's, this cannot be easily done. However, $\hat{Q}$ can be easily minimized with respect to μ_i 's. It is known that when n is large, the solution obtained by minimizing $\hat{Q}$ is close to the solution obtained by minimizing Q . This method, known as *sample average approximation*, is widely used in stochastic programming [5].

Let $\mu = (\mu_1, \dots, \mu_p)'$. Assume that the nominal values can be changed by at most 25% of the existing values given in Table 1. Minimizing $\hat{Q}$ subject to the

above constraints on μ_i , we obtain

$$\mu^* = (0.075, 0.375, 0.125, 0.125, 1.319, 14.183, 0.655)' \quad (5)$$

The average quality loss at the above setting is ¥756 per product, which is almost one-third of that of the existing design. Suppose that this is still large and we want to reduce it further; We can now consider tolerance design.

Tolerance Design

Taguchi's Approach

The quality loss can be reduced by tightening the tolerances. Tighter tolerances can be achieved by using better-quality raw materials, or by instituting better control devices, or by rejecting/reworking products falling outside the specifications. All of these increase the manufacturing cost. Therefore the decision of tightening tolerances should be made carefully so that the desired quality improvement can be achieved without unduly increasing the cost.

The manufacturing costs per product for three classes of tolerances are given in Table 2. We need to decide which tolerances should be tightened? By looking at Table 2, we may think that the tolerances of x_1 , x_6 , and x_7 should be tightened, because these

Table 2 Tolerance costs and model parameters

Factors	Costs			Model parameters		
	$\pm 25\%$	$\pm 12.5\%$	$\pm 2.5\%$	A	B	γ
x_1	10	25	100	-17.09	11.22	0.6357
x_2	20	50	200	-34.18	22.45	0.6357
x_3	20	50	200	-34.18	22.45	0.6357
x_4	50	100	500	0	12.5	1
x_5	50	200	1000	-196.06	94.97	0.6867
x_6	10	25	100	-17.09	11.22	0.6357
x_7	10	25	100	-17.09	11.22	0.6357

are least expensive. But if they do not have much effect on the response, then we may not get the required improvement in the quality. Thus, to take a judicious decision on which tolerances should be tightened, we need to know the contribution of each factor to quality. Taguchi [1] proposed to find this using **orthogonal array** experiments.

An 18-run orthogonal array [1] is given in Table 3, which can accommodate the seven factors. The three levels of each factor x_i can be chosen as a representative sample from $\mathcal{N}(\mu_i^*, \sigma_i^2)$. If we take the three levels as

$$\mu_i^* - \sqrt{\frac{3}{2}}\sigma_i, \mu_i^*, \text{ and } \mu_i^* + \sqrt{\frac{3}{2}}\sigma_i \quad (6)$$

Table 3 18-run orthogonal array and data

Run	x_1	x_2	x_3	x_4	x_5	x_6	x_7	y
1	1	1	1	1	1	1	1	1.60
2	1	2	2	2	2	2	2	1.26

x_7	2	0.060	5.5
Error	3	0.001	0.0
Total	17	1.089	100

then the mean and variance of these three values will be exactly μ_i^* and σ_i^2 . The function in equation (1) is evaluated for the 18 runs and is given in Table 3. The analysis of variance is shown in Table 4. The contribution of each factor is calculated as the ratio of its **sum of squares** to the total sum of squares. We can see that x_1 is the most important factor followed by x_5 , x_3 , and x_2 . Because tightening the tolerance of x_5 is very costly, it makes sense to focus on the tolerances of x_1 , x_2 , and x_3 . The decision about how much to tighten can be determined by comparing the reduction in quality loss with the increase in the manufacturing costs. This requires additional calculations, which will not be presented here. Instead, we present in the next section a more general and flexible method based on Monte Carlo simulations. However, we should point out that Taguchi's approach is much superior to the traditional tolerancing methods, such as worst-case and root sum-of-squares methods. See [1, 6] for details.

Monte Carlo Approach

Let $\delta_i = \sigma_i e_i$. Thus, we have $x_i = \mu_i + \sigma_i e_i$, where $e_i \sim \mathcal{N}(0, 1)$. Again assume that $t_i = 3\sigma_i$. We should explain the implications of this assumption. Tolerance represents the allowable variation not the actual variation. The actual variation in x_i could be more than t_i , in which case we assume that additional effort will be put into the process for reducing the variation so that $3\sigma_i = t_i$. On the other hand, if the actual variation is less than t_i , then by assuming $t_i = 3\sigma_i$ we underestimate the quality. Thus under this assumption, we are considering the worst-case scenario in terms of quality.

As in the case of the cyclone design example, sometimes it is more appropriate to express the tolerances as a percentage of their nominal values. Define $a_i = t_i/\mu_i$. Then $\sigma_i = \mu_i a_i/3$. Thus the average quality loss after parameter design can be computed as

$$\begin{aligned} Q &= E[L(Y)] = E[f(\mu_1^* + \sigma_1 e_1, \dots, \mu_p^* + \sigma_p e_p) - \tau]^2 \\ &= E\left[f\left(\mu_1^* + \frac{\mu_1^* a_1}{3} e_1, \dots, \mu_p^* + \frac{\mu_p^* a_p}{3} e_p\right) - \tau\right]^2 \end{aligned} \quad (7)$$

We also need to obtain an expression for the cost of changing tolerances. Let $c_i(a_i)$ be the cost of

4 Tolerance Design

manufacturing a product with tolerance for the i th factor equal to $t_i = a_i \mu_i$. Thus the total cost of manufacturing is

$$C = \sum_{i=1}^p c_i(a_i) \quad (8)$$

For the cyclone design the costs for each factor are given for three different tolerances. It is more convenient to use a continuous function for the costs. Many cost–tolerance models are given in [7]. We use the following model

$$c_i(a_i) = A_i + \frac{B_i}{a_i^{\gamma_i}} \quad (9)$$

The three parameters A_i , B_i , and γ_i can be deduced from the cost data in Table 2 and are also reported in the same table. The actual estimation of the tolerance costs can be tedious; see [8] for another example.

In [2, 3] the cost of the existing design is adjusted to zero. To be consistent with their approach, we reparameterize the cost function as

$$c_i(a_i) = \bar{A}_i + B_i \left(\frac{1}{a_i^{\gamma_i}} - \frac{1}{\bar{a}_i^{\gamma_i}} \right) \quad (10)$$

where $\bar{a}_i$ denotes the tolerance for the existing design and $\bar{A}_i$ the corresponding cost. We then let $\bar{A}_i = 0$.

Our objective is to find the optimal tolerances $a_1, \dots, a_p$ that minimize $Q + C$. For optimization we use the Monte Carlo approach described before. Thus the problem is to

$$\begin{aligned} & \min_{a_1, \dots, a_p} \frac{k}{n} \\ & \times \sum_{j=1}^n \left[f \left(\mu_1^* + \frac{\mu_1^* a_1}{3} e_{1j}, \dots, \mu_p^* + \frac{\mu_p^* a_p}{3} e_{pj} \right) - \tau \right]^2 \\ & + \sum_{i=1}^p c_i(a_i) \end{aligned}$$

The optimal solution is given by $\mathbf{a}^* = (0.073, 0.125, 0.122, 0.25, 0.197, 0.138, 0.145)'$. As expected, the largest decrease in the tolerance is for x_1 followed by x_2 and x_3 . No change is made for the tolerance of x_4 because its contribution to quality is negligibly small. At the optimal setting, the quality loss is obtained as ¥251 per product, which is one-third of the quality loss obtained after parameter design. However, the

cost of tolerancing is increased by ¥160 per product. The total cost of ¥411 per product is still much lower than the total cost after parameter design.

We note that the optimal solution obtained here is much better than that given in [2, 3]. This is because we have used a continuous cost–tolerance model, which gives more flexibility than using some discrete choices for the tolerances.

An important assumption in carrying out the Monte Carlo approach is that the function $f(x_1, \dots, x_p)$ is easy to evaluate. Although this is true for the cyclone design example, it need not be the case always. For example, the function could be implicitly defined through a finite element model, which can be quite time consuming to evaluate. In such cases, the function should be approximated by a metamodel using techniques, such as kriging (see **Computer Experiments**). Because the metamodel is easy to evaluate, the Monte Carlo approach can be efficiently implemented. When analytic or finite element models are not available, physical experiments should be carried out to estimate the function. In physical experiments, it is difficult to incorporate all of the external noise factors, and thus an error term should be included in the model: $y = f(x_1, \dots, x_p) + \epsilon$, where $\epsilon \sim \mathcal{N}(0, \sigma^2)$. Note that σ^2 can also depend on $x_1, \dots, x_p$. This will change the evaluation of the average quality loss, but everything else in the procedure remains the same.

The estimation of Q can be improved by using better sampling techniques, such as **Latin hypercube** sampling. Even better space filling designs are now available (see **Computer Experiments; Latin Hypercube Designs**).

Integrated Parameter and Tolerance Design

The parameter design solution was obtained by fixing the tolerances at the existing values. The optimal tolerances are then obtained by fixing the nominal values at the parameter design solution. Clearly, the parameter design solution that we obtained is not optimal anymore because the tolerances are different. We can go back and perform the parameter design optimization again with the new tolerances. This iterative process can be continued until convergence [9]. A more straightforward approach is to optimize the total cost simultaneously with respect to both nominal

Table 5 Comparison of different designs

Design	Nominal and tolerance values							Mean	Variance	Q	C	$Q + C$
Existing	0.10 0.25	0.30 0.25	0.10 0.25	0.10 0.25	1.50 0.25	16 0.25	0.75 0.25	1.76	0.120	2096	0	2096
Parameter	0.075 0.25	0.375 0.25	0.125 0.25	0.125 0.25	1.319 0.25	14.2 0.25	0.655 0.25	1.45	0.066	756	0	756
Tolerance	0.075 0.073	0.375 0.125	0.125 0.122	0.125 0.25	1.319 0.197	14.2 0.138	0.655 0.145	1.44	0.019	251	160	411
Integrated	0.075 0.071	0.375 0.120	0.125 0.120	0.125 0.25	1.176 0.189	16 0.131	0.685 0.137	1.49	0.019	209	177	386

and tolerance values [3]. Thus the problem is to

$$\min_{\mu_1, \dots, \mu_p, a_1, \dots, a_p} \frac{k}{n} + \sum_{j=1}^n \left[f\left(\mu_1 + \frac{\mu_1 a_1}{3} e_{1j}, \dots, \mu_p + \frac{\mu_p a_p}{3} e_{pj}\right) - \tau \right]^2 + \sum_{i=1}^p c_i(a_i) \quad (11)$$

We note that some combinations of μ_i 's and a_i 's can generate infeasible solutions. For example, in the cyclone design x_2/x_4 should lie within [1.2, 6.2], otherwise negative values will be produced inside the square root leading to infeasible solutions. Therefore special care should be taken during simulations to avoid such values.

The optimal solution is obtained as $\mu^* = (0.075, 0.375, 0.125, 0.125, 1.176, 16, 0.685)'$ and $a^* = (0.071, 0.120, 0.120, 0.25, 0.189, 0.131, 0.137)'$. The total cost is ¥386 per product, which is lower than what we obtained after the two-stage parameter and tolerance designs. Thus, as expected, the integrated approach performs better than the two-stage approach. For comparison, the results are summarized in Table 5.

Bergman–Hynén Method for Dispersion Effects

Introduction

During the last decades, **robust design** experimentation has become an important part of industrial statistics, see, for example, Wu and Hamada [1], Myers and Montgomery [2], Robinson *et al.* [3] and Myers *et al.* [4]. Dispersion analysis is of specific interest in robust design experimentation, where the objective is to find design solutions that make products with minimal dispersion (*see* **Dispersion Effects**).

Finding **dispersion effects** from unreplicated two-level **fractional factorial** designs has attracted much interest since the seminal paper by Box and Meyer [5]. The Box–Meyer method is based on a test statistic containing the ratio of the residual **sum of squares** connected with the high and low levels of each factor (*see* **Box–Meyer Method for Dispersion Effects**). The drawback of this method is that the sums of squares in the numerator and denominator are correlated as they are calculated from the same location model. Consequently, Box–Meyer’s method does not contain any formal statistical test to identify active dispersion effects.

Recently, a large number of papers on the identification of dispersion effects have given interesting generalizations, complements, and alternatives to the methods suggested by Box and Meyer [5]; see, for example, Engel and Huele [6], Bergman and Hynén [7], Nelder and Lee [8], Blomkvist *et al.* [9], Holm and Wiklander [10], Pan [11], Arvidsson *et al.* [12], Brenneman and Nair [13], McGrath and Lin [14, 15], McGrath [16], and Arvidsson *et al.* [17]. The purpose of this paper is to elaborate on the usefulness and limitations of the method for dispersion analysis suggested in Bergman and Hynén [7]. The next section presents the model and notation used throughout. The section titled “Identification of Dispersion Effects” presents two different ways of representing the Bergman–Hynén method, whereas aspects of modelling are discussed in the section following it. The discussion in the last section elaborates on the usefulness of the method.

Model and Notation

Let $\mathbf{y}$ denote an $n \times 1$ response vector from a 2^{k-p} fractional factorial experiment and $\mathbf{X} = [\mathbf{x}_0 | \dots | \mathbf{x}_{n-1}]$ the corresponding saturated $n \times n$ design matrix. Here, $\mathbf{x}_0 = \mathbf{1}$ is an intercept column of +1’s, and $\mathbf{x}_1, \dots, \mathbf{x}_{n-1}$ are orthogonal columns of +1’s and –1’s corresponding to the high and low levels of the factors and interactions. We assume a linear location model $\mathcal{L}$ with $k_{\mathcal{L}}$ parameters:

$$\mathbf{y} = \mathbf{X}_{\mathcal{L}}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (1)$$

where $\mathbf{X}_{\mathcal{L}}$ is an $n \times k_{\mathcal{L}}$ orthogonal design matrix containing the intercept column together with $k_{\mathcal{L}} - 1$ columns in $\mathbf{X}$. Here $\boldsymbol{\beta}$ denotes a vector containing the $k_{\mathcal{L}}$ regression coefficients and $\boldsymbol{\varepsilon}^T = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_n)$ an error vector of independent and normally distributed deviations with means zero. In addition to the location model we assume a dispersion model such that the variances of $\boldsymbol{\varepsilon}$ are $\sigma_j^2 = \mathbf{Z}_j\boldsymbol{\gamma}$, $j = 1, \dots, n$. Here, $\mathbf{Z}$ is an $n \times k_{\mathcal{D}}$ orthogonal matrix containing an intercept column together with $k_{\mathcal{D}} - 1$ columns in $\mathbf{X}$ related to factors that influence the dispersion. Further, $\mathbf{Z}_j$ are the corresponding row vectors, and $\boldsymbol{\gamma}$ is a $k_{\mathcal{D}} \times 1$ vector including dispersion coefficients. If **estimation** of the parameters in $\boldsymbol{\gamma}$ is focused, it is necessary to add the constraint $\sum_{i=1}^{k_{\mathcal{D}}-1} |\gamma_i| < \gamma_0$ on the dispersion coefficients.

Identification of Dispersion Effects

The Bergman–Hynén method for dispersion effect identification can be represented in a number of different ways. In this section, the residual-based representation is reviewed to point out similarities and differences with the Box–Meyer method. Further, a representation based on half contrasts is reviewed.

The Extended Location Model Representation

Let $\mathcal{L}_i^E$ denote an expanded location model that in addition to all factors and interactions in $\mathcal{L}$ contains all interactions between factor i and the factors and interactions in $\mathcal{L}$. Further, let $\tilde{r}_i$ denote the **residuals** corresponding to this expanded location model. The test statistic of the Bergman–Hynén method can then be written as follows:

$$D_i^{\text{BH}} = \frac{\sum \tilde{r}_{i+}^2}{\sum \tilde{r}_{i-}^2} \quad (2)$$

where $\tilde{r}_{i+}$ and $\tilde{r}_{i-}$ are the residuals of the expanded location model associated with the high and low levels of i , respectively. The test statistic of factor i can be calculated if $n > 2(k_L - k_i)$, where k_i is the number of pairs in $\mathcal{L}$ whose interaction is i (see, e.g., [13]). The main difference between D_i^{BH} and the Box–Meyer test statistic is that an expanded location model is used for calculating the residuals of factor i . The advantage of this innovation is that the residuals associated with the high and low levels of i are uncorrelated provided that no dispersion effects exist. This is an important property as it increases the test efficiency.

The Half-contrast Representation

Let $\mathbf{X}_{\mathcal{L}_i^E}$ be the design matrix corresponding to $\mathcal{L}_i^E$ and let $\mathbf{X}_{\tilde{\mathcal{L}}_i^E}$ contain the remaining columns of the saturated design matrix $\mathbf{X}$. Further, let $\mathbf{x}_i$ denote the column in $\mathbf{X}$ corresponding to factor i and $\text{diag}(\mathbf{x}_i)$ the corresponding diagonal matrix. Then

$$\begin{aligned} \mathbf{P}_{i+} &= \frac{1}{2}(\mathbf{I}_n + \text{diag}(\mathbf{x}_i)) \text{ and} \\ \mathbf{P}_{i-} &= \frac{1}{2}(\mathbf{I}_n - \text{diag}(\mathbf{x}_i)) \end{aligned} \quad (3)$$

are diagonal matrices partitioning $\mathbf{X}$ into two matrices $\mathbf{P}_{i+}\mathbf{X}$ and $\mathbf{P}_{i-}\mathbf{X}$ corresponding to high and low levels of i , respectively.

Now, let the m th column in $\frac{1}{\sqrt{n}}\mathbf{P}_{i+}\mathbf{X}_{\tilde{\mathcal{L}}_i^E}$ be denoted $\mathbf{V}_{i+,m}$ and define the contrast $v_{i+,m} = \mathbf{V}_{i+,m}^T \mathbf{y}$; further, define $v_{i-,m}$ similarly. We now have

$$D_i^{\text{BH}} = \frac{\sum_{m \in \tilde{\mathcal{L}}} v_{i+,m}^2}{\sum_{m \in \tilde{\mathcal{L}}} v_{i-,m}^2} \quad (4)$$

As shown in Bergman and Hynén [7], $v_{i+,m}$ and $v_{i-,m}$ correspond to $n/2 - (k_L - k_i)$ pairs of independent contrasts not involved in the location model. Thus, their expected values are zero and their variances are $V(v_{i+,m}) = \sigma_{i+}^2/2$ and $V(v_{i-,m}) = \sigma_{i-}^2/2$, respectively; note that $\sigma_{i+}^2 = 2n^{-1} \sum_{x_{j,i}=+1} \sigma_j^2$, where $\mathbf{x}_{j,i} = +1$ indicates summation over the high levels of $\mathbf{x}_i$, and σ_{i-}^2 is defined correspondingly. Thus, under the assumption that experiments contain no dispersion effects $D_i^{\text{BH}} \sim F(n/2 - (k_L - k_i), n/2 - (k_L - k_i))$ and formal **hypothesis testing** can be used to investigate whether i has a dispersion effect or not.

The equivalence of the two representations of Bergman–Hynén’s method follows immediately from the result within linear models that the sum of squared residuals is equal to the sum of squares of contrasts not included in the model, see Rao [18].

Modeling Aspects

A common practice is to assume log-linear dispersion models. In these models, the expected value is described as a linear function of the factor levels and the variance is modeled as a log-linear function of the factor levels. This is a convenient model because it makes estimated variances necessarily positive. However, this argument is not very strong when estimates are derived merely to provide support for the identification of factors affecting dispersion. In these cases, differences in the magnitude of the estimates are a more important aspect than the actual values of the estimates. Furthermore, the physical interpretation of the log-linear model is not clear. Arvidsson *et al.* [17] argue that it is unnatural to use different link functions for the expected value and the variance in the robust design framework. The rationale of this argument is that dispersion effects are assumed to be interactions between design factors and noise factors not systematically varied in the experiment. Therefore, the application of log-linear dispersion models might be questioned in robust design experimentation.

It should be noted that multiplicative models could be assumed in many engineering situations. However, these models are easily transformed into additive models by taking logarithms of the raw data before fitting any models. Of course, additional types of scale transformations might also be necessary in order to achieve an additive model. The point is that we want to analyze the overdispersion in the model, that is, dispersion not attributable to a scale transformation. (For related discussions, see León *et al.* [19], Box [20], and **Performance Measures for Robust Design**.) In summary, our proposal for modeling robust design experiments, possibly after a scale transformation, is a linear location model $\mathcal{L}$. This location model is complemented with a linear variance model interpreted as interactions between design factors and unknown or nonobserved noise factors.

Brenneman and Nair [13] showed that the appropriateness of different methods for dispersion effect

identification depends on the assumed variance model. McGrath and Lin [14] and Brenneman and Nair [13] showed that the Bergman–Hynén test statistic is biased under the log-linear variance model if multiple dispersion effects exist. However, this is not the case when an additive variance model is assumed.

Discussion

The assumption of a correctly identified location model is a common denominator in all methods for identification of dispersion effects in unreplicated fractional factorials. If this assumption is inaccurate, **aliasing** between location and dispersion effects may complicate the identification. In fact, McGrath and Lin [15] showed that two unidentified location effects create a spurious dispersion effect in their interaction column. McGrath [16] proposed two procedures for determining whether a dispersion effect is real or whether it actually stems from two unidentified location effects. Moreover, Bisgaard and Pinho [21] discussed possible follow-up strategies to investigate whether identified dispersion effects are actually due to aberrant observations or faulty execution of some of the experimental runs.

One aspect of the identification procedure suggested by Bergman and Hynén [7], not addressed in this paper, is the situation that appears when multiple dispersion effects exist. In those cases it is easily seen that the half contrasts in the numerator and denominator of the test statistic are correlated. Thus, the test statistics will not be F distributed. One way to address this problem is to adopt the idea of McGrath and Lin [14] to partition the experiment with respect to the levels of all factors expected to influence dispersion. This extended partitioning of the experiment is done to obtain uncorrelated test statistics, thus making a subsequent testing or normal plotting strategy more adequate. A problem that may occur when pursuing this strategy is that there will be few **degrees of freedom** for dispersion effect testing. However, a continuation of these ideas must be postponed to future research.

MARTIN ARVIDSSON AND BO BERGMAN

Box–Meyer Method for Dispersion Effects

Introduction

During the process of new product development, we run engineering experiments to optimize both product design and manufacturing processes. An example of developing the tablet for a new drug product illustrates the concept. Using **factorial** and **response surface** designs, we vary the levels of inert ingredients in the formulation, as well as process variables such as roller compaction speed and pressure. The results of the experiments allow us to set the values of these variables in the product/process design, in order to optimize features such as product shelf life. Typical designs employed in earlier stages are 2^{k-p} factorial or fractional factorial designs (*see Fractional Factorial Designs*), which are followed by response surface designs (*see Response Surface Methodology*) in the search for optimum settings.

One aspect of product quality we are often concerned with is minimizing variability of finished product. In the 1980s Taguchi [1] and others showed us that the product design has a major influence on this variability. Taguchi also showed how the same engineering experiments used to optimize product features could also be used to reduce variability, or dispersion. As an alternative to the Taguchi **signal-to-noise** approach, the concepts of location effects and **dispersion effects** were developed [2] to separate the ideas of factors affecting mean performance of the product and factors affecting the variability of the product, respectively. Specifically, the Box–Meyer method was introduced for identifying dispersion effects from unreplicated and fractionally replicated designs.

Method

The concept of dispersion effects and dispersion modeling can be applied to designs with any number of factors and levels. (For general theory *see Generalized Linear Models*.) The Box–Meyer method was devised for two-level designs such as 2^{k-p} (*see Fractional Factorial Designs*) and Plackett–Burman designs (*see Plackett–Burman Designs*), where k

is the number of experimental factors and n the number of runs. For these designs, we typically have $n - 1$ orthogonal columns of +1's and -1's, labeled $\mathbf{x}_1, \dots, \mathbf{x}_{n-1}$. We use k of the columns to vary the experimental factors in the design. Contrasts calculated from these k columns estimate main effects (with possible confounding with interactions). The remaining unused columns estimate interactions among two or more factors (*see Aliasing in Fractional Designs*).

After we run our two-level fractional designed experiment, location effects are identified in the usual way by any number of methods, for example, half-normal **probability plot** of effects (*see Half-Normal Plot*) or Lenth's method (*see Lenth's Method for the Analysis of Unreplicated Experiments*). Location effects can include both main effects and interactions. Once active location effects are identified, we fit a linear regression model to the data, incorporating those effects. The statistical model is as follows:

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (1)$$

Here $\mathbf{Y}$ is the vector of response variable measurements, $\mathbf{X}$ is the matrix corresponding to active location effects and includes a column for the intercept, $\boldsymbol{\beta}$ is the vector of regression coefficients, and $\boldsymbol{\varepsilon}$ is the vector of errors assumed to be normally distributed with zero mean. We estimate regression coefficients by ordinary least squares (*see Least-Squares Estimation*):

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y} \quad (2)$$

The residuals (*see Residuals*), $\mathbf{e}$, from this fit are then used to identify and estimate the dispersion effects.

$$\mathbf{e} = \mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}} \quad (3)$$

For each of the $n - 1$ orthogonal columns $\mathbf{x}_i$ in the original design, the estimated dispersion effect is defined as

$$F_i = \frac{\sum_{j:\mathbf{x}_i=+1} e_j^2}{\sum_{j:\mathbf{x}_i=-1} e_j^2} \quad (4)$$

This is the sum of squared residuals for those runs with $\mathbf{x}_i$ at its high level (+1), divided by the sum of squared residuals for those runs with $\mathbf{x}_i$ at its low level (-1). There will be k dispersion main effects, and $n - 1 - k$ interaction dispersion effects.

2 Box–Meyer Method for Dispersion Effects

Dispersion effects F_i either much greater than 1 or much less than 1 indicate potentially significant effects.

It is important to note that, in general, under the null hypothesis of no dispersion effect, one cannot assume that F_i necessarily follows an F distribution. To identify those estimated dispersion effects that may be important, the logarithms of the estimated dispersion effects can be plotted on a **half-normal plot** to identify those that stand out from the others.

Example

A nine-factor two-level study of welding comes from [1]. The design and responses are shown in Table 1. Factors B and C have significant location effects. After calculating residuals from the regression model with those location effects, dispersion effects were calculated from the residuals. Table 2 shows in detail how the dispersion effect for factor C is calculated. A half-normal plot of the natural logarithm of all the

estimated dispersion effects is shown in Figure 1. The estimates are given in Table 3. One could conclude a possible dispersion effect of factor *C* (welded material). In other words, variability in tensile strength of the weld appears to be higher for one of the welded materials than for the other.

Strengths of the Technique

Ordinarily, experiments to study dispersion would require repeated runs. Much larger experiments would be needed. The Box–Meyer technique can be applied to two-level unreplicated factorial and fractional factorial designs. So a major advancement of

Box and Meyer was just recognizing that dispersion effects could be estimated from unreplicated designs.

The Box–Meyer method is very simple to understand, very easy to apply, and intuitive. While there are other methods that have been developed for estimating dispersion effects in two-level designs (*see Bergman–Hynén Method for Dispersion Effects; Harvey’s Method for Dispersion Effects*), they are more complicated and typically the estimates are similar.

Weaknesses of the Technique

Application of the method is limited to two-level orthogonal designs, though extensions to more than two levels are straightforward. Modeling dispersion effects in more complex situations, for example, when important covariates must be included in the modeling, requires other more advanced methods such as generalized linear models (*see Generalized Linear Models*). Also, making inferences about dispersion from an unreplicated design is a risky proposition. Conservative scientists may find this an uncomfortable situation. Thus dispersion effects discovered in this manner would more reliably be verified in a confirmatory experiment that included repeat runs. Alternatively, analyzing replicated experiments for dispersion effects is described in [3].

As described in the original article [2], there is an **aliasing** relationship between dispersion effects and location effects in unreplicated designs. One can easily show that estimated dispersion effects are a simple quadratic function of the estimated location effects assumed to be inert (and not included in the location model). This is not a major problem, but real location effects assumed to be inert could falsely dampen or inflate the size of estimated dispersion effects [4].

The Box–Meyer technique does not include a tractable null distribution to judge the statistical significance of potential dispersion effects. The Bergman–Hynén dispersion effect method [5] is a similar method in which the null distribution can be shown to be the usual *F* distribution (under a null hypothesis of no dispersion effects). This allows a statistical test of the null hypothesis of no effect, and construction of an *F*-based **confidence interval** for the dispersion effect.

4 Box–Meyer Method for Dispersion Effects

When a substantial number of effects are included in the location model (1) above, the **degrees of freedom** for estimating dispersion effects are reduced. One should exercise even more caution in interpreting the dispersion effects in these situations.

Generalized Linear Models

Overview of the Linear Regression Model

“All models are wrong; some models are useful.” This quote from the eminent statistician George Box attempts to put modeling into the proper perspective. While no mathematical model can describe nature exactly, some models do a better job than others. Indeed, we often state assumptions that were made in order to estimate the parameters of our model or to perform some inference knowing in our heart that they do not hold. We rely on the procedure being robust to these assumptions, or assume that they are met asymptotically (i.e., never in practice but close for large data sets). We sometimes start with a model and if there appears to be a disagreement between the model and the data, we change the data through some transformation, known more softly as *reexpression*.

The standard linear regression model is

$$y_i = \beta_0 + \beta_1 x_{i1} + \cdots + \beta_k x_{ik} + \epsilon_i \quad (1)$$

where $E(\epsilon_i) = 0$, $\text{Var}(\epsilon_i) = \sigma^2$, and $\text{Cov}(\epsilon_i, \epsilon_j) = 0$ for $i \neq j$. For notational purposes, we will abbreviate the term linear regression model as LM in this exposition.

In matrix notation, $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$ where

$$\begin{aligned} \mathbf{Y} &= \begin{pmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{pmatrix}, \mathbf{X} = (\mathbf{1}, \mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k) \\ &= \begin{pmatrix} 1 & x_{11} & x_{12} & \cdots & x_{1k} \\ 1 & x_{21} & x_{22} & \cdots & x_{2k} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & x_{n1} & x_{n2} & \cdots & x_{nk} \end{pmatrix}, \\ \boldsymbol{\beta} &= \begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_k \end{pmatrix}, \boldsymbol{\epsilon} = \begin{pmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_n \end{pmatrix} \end{aligned} \quad (2)$$

So $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta} = \boldsymbol{\mu}$ and $E(y_i) = x_i'\boldsymbol{\beta} = \mu_i$. Here, $x_i'\boldsymbol{\beta}$ is called the *linear predictor*. In the ordinary least-squares (OLS) approach, we find our vector of estimates, $\mathbf{b}$, of $\boldsymbol{\beta}$ by minimizing the sum of the squared **residuals**, $Q = \sum_{i=1}^n e_i^2 = \sum_{i=1}^n (y_i - x_i'\boldsymbol{\beta})^2$ which, in matrix notation is $Q = (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})$.

The minimum is found by differentiating Q with respect to $\boldsymbol{\beta}$ and equating to 0: $\partial Q / \partial \boldsymbol{\beta} = -2\mathbf{X}'\mathbf{Y} + 2\mathbf{X}'\mathbf{X}\boldsymbol{\beta} = \mathbf{0}$. Note that this may also be expressed as $\mathbf{X}'(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}) = \mathbf{0}$ or

$$\mathbf{X}'(\mathbf{Y} - \boldsymbol{\mu}) = \mathbf{0} \quad (3)$$

Solving this set of linear equations results in

$$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{Y} \quad (4)$$

In order to perform inference about the parameters, or to calculate interval estimates of predictions, a normality assumption is often made. If we assume the error terms follow a multivariate **normal distribution** with common variance and no **correlation**, then we have $\boldsymbol{\epsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I}_n)$ where $\mathbf{I}_n$ is the $n \times n$ identity matrix. For convenience, we will drop the subscript n when the dimension is obvious.

Another popular method for finding $\mathbf{b}$ is maximum-likelihood **estimation** (MLE). Under the normality assumption described above, we can write the likelihood function as

$$\begin{aligned} l(\mathbf{Y}, \boldsymbol{\beta}, \sigma^2) &= (2\pi\sigma^2)^{-n/2} \exp(-(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}) \\ &\quad \times (2\sigma^2)^{-1}) \end{aligned} \quad (5)$$

The maximum-likelihood estimators of $\boldsymbol{\beta}$ and σ^2 of course maximize the likelihood, or equivalently, the natural logarithm of the likelihood commonly called *log-likelihood* or $\log(l)$. (We use the designation *log* to represent the natural logarithm throughout.) The derivative of $\log(l)$ is known as the *score function* or simply the *score*. Differentiating $\log(l)$ and equating to 0 we have $\partial \log(l) / \partial \boldsymbol{\beta} = (2\sigma^2)^{-1} (-2\mathbf{X}'\mathbf{Y} + 2\mathbf{X}'\mathbf{X}\mathbf{b}) = \mathbf{0}$ which simplifies to $\partial \log(l) / \partial \boldsymbol{\beta} = \mathbf{X}'(\mathbf{Y} - \boldsymbol{\mu}) = \mathbf{0}$. Thus, the maximum-likelihood estimators are the same as those obtained by **least squares**.

If the normality assumption does not hold, we often transform the data, $\mathbf{y}$ to $g(\mathbf{y}) = \mathbf{y}'$ so that the errors more closely resemble a normal distribution. Box-Cox transformations (see **Box and Cox Transformation** and Box and Cox [1]) comprise a family of power transformations that are used frequently in practice.

Introduction to Generalized Linear Models

In this section, we first define the *generalized linear model* (GLM) and then discuss inference and

2 Generalized Linear Models

diagnostic procedures. For a full treatment of GLMs, see the classic text of McCullagh and Nelder [2]. For practitioners in the quality and reliability fields, see Myers *et al.* [3] for a more applied introduction.

The idea behind GLMs is to use a distribution that more naturally models the response instead of “forcing” normality. The distributions that can be employed in GLMs are members of the exponential family. Many common distributions are members of this family including, in addition to the normal, the binomial, Poisson, exponential, and gamma distributions. For these distributions, the probability density function (pdf) may be written as

$$f(y; \theta, \phi) = \exp(a(\phi)^{-1}(y\theta - b(\theta)) + c(y, \phi)) \quad (6)$$

It can be shown that for any random variable Y with a density of the above form,

$$E(Y) = \mu = b'(\theta) \quad (7)$$

and

$$\text{Var}(Y) = b''(\theta)a(\phi) = \frac{d\mu}{d\theta}a(\phi) \quad (8)$$

An advantage of GLMs is that, for example, data that seem to be modeled well by the binomial distribution can be analyzed using the binomial itself instead of transforming to the normal distribution. In GLMs, we use a transformation of μ_i , not of y_i . In other words, we let $\eta_i = g(\mu_i)$ where $g(\cdot)$, called the *link function*, is monotone and differentiable. The function $\eta_i = g(\mu_i) = \theta_i$ is known as the *canonical link*. Using the Poisson distribution as an example we have

$$f(y; \lambda) = \lambda^y \exp(\lambda)(y!)^{-1} = \exp((y \log(\lambda) - \lambda) \times (1 - y!)^{-1}) \quad (9)$$

so $\theta = \log(\lambda)$, $b(\theta) = -\lambda = \exp(-\theta)$, $\phi = 1$, $a(\phi) = 1$, and $c(y, \phi) = y!$. The canonical link is then $\eta_i = g(\mu_i) = \log(\lambda_i)$, that is, the log link. While other links may be (and are) used, selection of the canonical link simplifies the mathematics. If a noncanonical link is used, the algorithm used to find our estimates is more complicated, but that need not concern us here. For a discussion of using noncanonical links, see [3, pp. 165–166].

So we have $\eta_i = g(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$, that is, that some function of the mean is related to the experimental

factors through a regression model. As in linear regression, an important goal is to estimate the parameters, $\boldsymbol{\beta}$ and we will use the maximum-likelihood approach to accomplish this. By restricting our attention to the exponential family, we note that $\log(l) = \sum_{i=1}^n a(\phi)^{-1}(y_i \theta_i - b(\theta_i)) + c(y, \phi)$ and using equation (7) we have $\partial \log(l) / \partial \theta_i = \sum_{i=1}^n a(\phi)^{-1}(y_i - b'(\theta_i)) = \sum_{i=1}^n a(\phi)^{-1}(y_i - \mu_i)$. If the canonical link is used, $\eta_i = \theta_i = \mathbf{x}_i' \boldsymbol{\beta}$ and $\partial \theta_i / \partial \boldsymbol{\beta} = \mathbf{x}_i'$. So, using the chain rule, we have $\partial \log(l) / \partial \boldsymbol{\beta} = (\partial \log(l) / \partial \theta) \times (\partial \theta / \partial \boldsymbol{\beta}) = \sum_{i=1}^n a(\phi)^{-1}(y_i - \mu_i) \mathbf{x}_i'$. Finally, equating these to 0 provides $\partial \log(l) / \partial \boldsymbol{\beta} = \sum_{i=1}^n (y_i - \mu_i) \mathbf{x}_i' = 0$, or, in matrix notation

$$\frac{\partial \log(l)}{\partial \boldsymbol{\beta}} = \mathbf{X}'(\mathbf{Y} - \boldsymbol{\mu}) = \mathbf{0} \quad (10)$$

which are the score equations. Although equation (10) appears to be identical to equation (3), there is a difference in $\boldsymbol{\mu}$. For the linear regression model (LM), we had $\mu_i = \mathbf{x}_i' \boldsymbol{\beta}$ which is linear in $\boldsymbol{\beta}$. This not generally true for GLMs. Referring back to our Poisson model in equation (9) with the log link function, we have $\log(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}$ or $\mu_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$ which is clearly nonlinear in $\boldsymbol{\beta}$. In general, there is no closed form solution to these score equations. Accordingly, we must use methods of nonlinear regression such as iteratively reweighted least squares. These methods will provide us with the GLM estimator $\mathbf{b}$ which can be shown to be asymptotically unbiased. To find the asymptotic **covariance** matrix of $\mathbf{b}$, we recall from equation (8) that $\text{Var}(Y_i) = \sigma_i^2 = (d\mu_i/d\theta_i)a(\phi)$ so that assuming zero correlation among responses we have $\text{Cov}(\mathbf{Y}) = \text{diag}(\sigma_i^2) = \mathbf{V}$. It can be shown that the asymptotic covariance matrix for $\mathbf{b}$ is

$$\text{Cov}(\mathbf{b})_{\text{can}} = (\mathbf{X}'\mathbf{V}\mathbf{X})^{-1} (a(\phi))^2 \quad (11)$$

Recall for the normal distribution we have $\mu_i = \theta_i$ and $a(\phi) = \sigma^2$. Therefore, $\mathbf{V} = \sigma^2 \mathbf{I}$ and we get the well-known result

$$\text{Cov}(\mathbf{b})_{lm} = (\mathbf{X}'\mathbf{X})^{-1} \sigma^2 \quad (12)$$

So the common LM assuming independent normally distributed errors can be viewed as a GLM using the normal distribution and an identity link, $\eta_i = \mu_i$. If a noncanonical link is used, the computations become more complex and the asymptotic covariance matrix becomes

$$\text{Cov}(\mathbf{b})_{\text{non}} = (\mathbf{X}'\Delta\mathbf{V}\Delta\mathbf{X})^{-1} \sigma^2 (a(\phi))^2 \quad (13)$$

where $\mathbf{\Delta}$ is a diagonal matrix with i th element $\partial\theta_i/\partial\eta_i$.

Given data Y_i that are independent with $E(Y_i) = \mu_i$, the steps for fitting a GLM are outlined here.

1. The distribution of Y_i is specified as a member of the exponential family as previously defined.
2. The linear predictor is $\mathbf{x}_i'\boldsymbol{\beta}$.
3. Some function of the mean equals the linear predictor, $\eta_i = g(\mu_i) = \mathbf{x}_i'\boldsymbol{\beta}$. The function $g(\mu_i)$ is called the *link function* as it “links” the mean to the linear predictor.
4. To find $\mathbf{b}$, the vector of estimators of $\boldsymbol{\beta}$, we must use iteratively reweighted least squares, or specialized GLM software.

Inference in Generalized Linear Models

In the general linear model, parameter inference is relatively straightforward due to the normality assumption. Indeed, the OLS and maximum-likelihood estimator of β_j is b_j with **standard error** $\text{SE}\{b_j\}$ and

$$t_j = b_j(\text{SE}\{b_j\})^{-1} \sim t_{(n-p)} \quad (14)$$

where $\text{SE}\{b_j\}$ is the j th diagonal term of $\text{Cov}(\mathbf{b})_{lm}$ and p is the number of parameters estimated. **Confidence intervals** for and hypothesis tests about β_j are constructed based on this distribution and the inference is exact under normality. Of course the normal distribution is merely a model of the real-life behavior and is therefore an approximation. Similar results are generally found when the data do not depart much from normality. In GLMs, we rely on an asymptotic approximation known as *Wald inference*, that is,

$$\chi_j^2 = (b_j(\text{SE}\{b_j\})^{-1})^2 \sim \chi_{(1)}^2 \quad (15)$$

where $\text{SE}\{b_j\}$ is the j th diagonal term of $\text{Cov}(\mathbf{b})_{can}$ or $\text{Cov}(\mathbf{b})_{non}$ depending on the category of link used. Note the similarity between equations (14) and (15). As $n - p$ increases without bound, $t_{(n-p)}$ approaches $N(0, 1)$, the square of which is $\chi_{(1)}^2$. For GLMs, the approximation may be considered rough for small values of $n - p$ where p is the number of parameters estimated.

Diagnostics in GLMs

In the linear model, $SSE = \sum_{i=1}^n (y_i - \hat{\mu}_i)^2 = \sum e_i^2$ is a measure of the variation unexplained by the

model. If a saturated model (one in which n parameters are estimated) is fit, then $SSE = 0$. So SSE is the difference between variation left from the fitted model and the saturated model. An analogous term in GLMs is called the *deviance*, which is a function of likelihoods. A saturated model will provide the maximum possible likelihood for the observed data. Any model with fewer parameters will have a smaller likelihood. The *deviance* is defined as

$$D = -2 [\log(l_{\text{fit}}) - \log(l_{\text{sat}})] \quad (16)$$

The subscripts “fit” and “sat” in equation (16) refer to the fitted and saturated models respectively. Since each $\log(l)$ is a sum of n components, we can write $D = \sum_{i=1}^n D_i$ where $D_i \geq 0$ and define the deviance residuals as $d_i = \text{sgn}(e_i)\sqrt{D_i}$ so that the deviance and traditional residuals have the same sign. These d_i may be used for diagnostic purposes as the e_i are used in LM. For example, a normal **probability plot** of e_i is often used to check the normality assumption in LMs. Significant departures from a line on this plot may suggest a transformation is warranted. Similarly, the d_i from a GLM may be plotted on a normal probability plot and significant departures from a line suggest consideration of another link function.

Generalized Linear Models in 2^{k-p} Experiments

GLMs have been employed successfully in many different areas such as the biological and social sciences. Often they are used in **observational studies** as an alternative to OLS estimation in multiple regression. In these studies, the predictor variables, the X 's, are not controlled but merely observed. Also, it is often known that the normal distribution provides a poor model for the response. However, in the engineering and physical sciences, experiments are often performed where the predictors are under the experimenter's control and it is often assumed that the normal distribution provides an adequate model. If there appears to be **skewness** or nonconstant variance, the data may be transformed, perhaps using a Box–Cox transformation (see [1]). GLMs may be applied in either of these settings as well as others. In this section, we will focus on the use of GLMs in two-level fractional factorial (2^{k-p}) designs (see **Fractional Factorial Designs**). We will discuss three uses of GLMs in such experiments: with attribute

4 Generalized Linear Models

data such as defects or defective counts, for identifying factors that affect the mean of a continuous response, and finally for estimating both mean (location) and variance (dispersion) effects for continuous responses.

Attribute Data

In many industrial experiments, it is prohibitively expensive, or even impossible, to use a quantitative variable or variables as quality characteristics. We may be forced into recording the number of defects on tested units or just the number of defective units (those having one or more defects). If m_i units are inspected in run i of an experiment, then the only possible values for the number of defective units are $0, 1, \dots, m_i - 1, m_i$. If we assume the probability of a unit being defective within an experimental run i is a constant, p_i , and that the units are independent, then the binomial distribution is a reasonable model. If y_i is the number of defective units in experimental run i and we let $\hat{p}_i = y_i m_i^{-1}$, then $0 \leq \hat{p}_i \leq 1$. Under a binomial model, $E(Y_i) = m_i p_i$ and $\text{Var}(Y_i) = m_i p_i (1 - p_i)$. Clearly the variance is a function of the mean. Assuming a normal distribution for values that are bounded can lead to predicted values that are not feasible, for example, greater than 1. In order to use an LM, some authors suggest using the transformation $\hat{p}' = \arcsin(\sqrt{\hat{p}})$. This is known as a *variance stabilizing transformation*. The data would be analyzed on this scale and then transformed back to the original for interpretation.

If the number of defects is the response, then we know the possible values for y_i are $0, 1, \dots$. If the defects are assumed to occur independently, then the Poisson distribution may provide a reasonable model. Using equation (9) for the Poisson distribution

we have $E(Y) = \lambda$ and $\text{Var}(Y) = \lambda$. Again, the variance is a function of the mean and the LM can produce undesirable values less than 0. To use an LM, the variance stabilizing transformation $y' = \sqrt{y}$ is often employed. As an alternative to these transformations, we can make use of GLMs, directly modeling the response with either the binomial or the Poisson distribution with an appropriate link function.

We now provide an example wherein each unit within a run is classified as acceptable or defective. The experiment is a 2^3 design with factors A , B , and C coded as -1 and $+1$ for their low and high levels respectively. In run i of the experiment, we observe y_i , the number of acceptable units out of the $m_i = m = 100$ units tested. Note that since m_i is a constant, yield may be described as number or percentage or fraction ($\hat{p}_i = y_i m_i^{-1}$) of acceptable units. We use three models: (a) LM on the observed data (LM1), (b) LM using the transformation $y' = \arcsin(\sqrt{\hat{p}_i})$ (LM2), and (c) a GLM with the binomial distribution and a logit link function (GLM). Letting $E(Y_i) = m_i p_i$ and $y_i m_i^{-1} = \hat{p}_i$, the logit link is $\log(p_i(1 - p_i)^{-1})$. The first four columns of Table 1 display the design for our example and the response y_i recorded as yield. Table 2 contains the parameter estimates as well as common inference output.

Analysis of the three models shows that factors A and B are active and that factor C most likely is not. AB is highly significant for the analysis on the original scale and is mildly significant on the transformed scale. For these models, we include A , B , and AB as active. For the GLM, AB had a p value of 0.66 and so only the main effects A and B were included. The parameter estimates in Table 2 were used to find the fitted values (reported as fraction acceptable) for each model. For LM1, the fitted values are simply obtained

Table 1 2^3 design with response and fitted values for each of three models

A	B	C	Yield	Original	Transformed	GLM
-1	-1	-1	30	0.320	0.325	0.320

(c)				
Predictor	Coefficient	SE coefficient	T	P
Intercept	1.2202	0.1022	142.57	0.000
A	1.0756	0.1005	114.44	0.000
B	0.8766	0.0965	82.43	0.000

by substituting the appropriate values of A and B and dividing by 100. The fitted values for LM2 were obtained as $\hat{p}_i = \sin^2(1.03071 + 0.212126A + 0.17028B - 0.04718AB)$ and for the GLM, $\hat{p}_i = e^{1.2202 + 1.0756A + 0.8766B} / (1 + e^{1.2202 + 1.0756A + 0.8766B})^{-1}$. These values from the three models occupy the last three columns of Table 1. Clearly, all three models give similar fitted values. All models suggest higher yields should occur at values of A and B greater than those studied, that is, outside the range of $(A, B) \in [-1, 1]^2$.

So what if we look outside the range of values studied? While extrapolation should always be done with caution, we will extrapolate here to see what happens to our predicted values beyond the range of data. Since LM1 and LM2 contain the AB interaction, we can find the values of A and B that give the maximum predicted yield. These are $(A, B) = (2.05, 2.56)$ and $(4.50, 3.61)$ for LM1 and LM2 respectively. While not extrapolating that far, Figure 1 shows $100\hat{p}_i$ as a function of A with $B = 1.5$ (for illustrative purposes) for each of the three models. Note that LM1 increases without bound (for fixed B), quickly surpassing the highest possible value of 100%. The transformation in LM2 avoids

**Figure 1** Estimated yield (in proportion) for three models. 1: LM on original data, 2: LM on arcsin transformed data, and G: GLM with binomial distribution and logit link

this problem, achieving its maximum of 100% near $A = 2$ for $B = 1.5$. The GLM, fit without an interaction, approaches 1 asymptotically. So the three models give similar results within the range of data studied, but differ substantially outside this range. While we cannot tell which provides the best fit between LM2 and GLM, the GLM model has the advantage of simplicity in that it fits the data well without including the interaction term.

Location Effects

As opposed to producing attribute (count) data, many industrial experiments have quantitative quality characteristics such as resistivity, voltage, diameter, and so on. While a normal distribution may provide a reasonable model for many such characteristics, others may be known to have a skewed distribution. For example, a simple model for measuring lifetimes in the reliability field is the exponential distribution. In other applications, tool wear often leads to skewed distributions of quality characteristics which can be modeled by the gamma distribution, of which the exponential is a special case.

Myers *et al.* [3, p. 176] provide an example of a 2^4 design to study the effects of four factors labeled X_1 , X_2 , X_3 , and X_4 on the response, resistivity. The design matrix is given in columns 1–4 of Table 3 with labels in the 2^4 row and the resistivity values in the y_1 column. They assumed, as we do, that the three and four factor interactions are negligible and are pooled into an error term for inference purposes. As resistivity is known to have a positively skewed distribution, we analyze the data using a log transformation on y , $y' = \log(y)$ with an LM. Table 4(a) shows edited output from SAS. As an alternative, we fit a GLM with a gamma distribution

and a log link and display edited output from SAS Proc Genmod in Table 4(b). The Appendix shows the SAS code (version 9.1) needed to perform these analyses. Note the similarities in the code.

We note that in part (a) of the table, t statistics from equation (14) are used for testing and in part (b) χ^2 statistics from equation (15) are used. Also, the parameter estimates are very similar, but the LM estimates have standard errors of 0.0206 compared to the asymptotic standard error of 0.0115 for the GLM estimates, a 44% reduction. This difference in standard errors results in drawing different conclusions from the two models. In the LM, X_1 , X_2 , and X_3 are clearly active and X_2X_3 and X_3X_4 show mild significance. However, in the GLM, X_1 , X_2 , X_3 , X_4 , X_1X_3 , X_2X_3 , and X_3X_4 are all highly significant. The addition of X_4 and noting that X_3 also interacts with X_1 was missed by the LM. Regardless of which model is used, we may choose to remove the nonsignificant terms and refit the model. After doing so, of course, we should use diagnostic procedures such as residual plots to assess each model. For the GLM, the deviance residuals (d_i)s may be used for this purpose. As previously mentioned, plots of the deviance residuals may display **outliers** or suggest investigation of a different link function. In the interest of brevity, we do not show these plots.

Location and Dispersion Effects

Experimenters have been interested in studying process means (location) for many years. Taguchi *et al.* [9] generated much interest in developing products and processes that are robust to noise. A **robust design** is one in which we observe little variation at the target value of the process. While there are many different approaches to accomplish this (see **Robust Design**), the general principle is to find factors that affect the variation in the response (**dispersion effects**) and set them at levels to minimize the variance. We then find factors that affect the mean of the response (location effects), but do not impact the variance, and set these to adjust to the desired target value of the response. The mechanics of doing so depend on whether the experiment is replicated or not.

As before, let $\mathbf{X}$ be a matrix whose first column consists of 1's and the rest be potential location effect columns. In a similar manner, let $\mathbf{Z}$ be a matrix whose

first column consists of 1's and the rest be potential dispersion effect columns. Often the columns in $\mathbf{Z}$ are a subset of those in $\mathbf{X}$ but this is not necessary. The generic model we will follow is given in equation (17).

$$Y_i = \mu_i + \epsilon_i, g(\mu_i) = \mathbf{x}_i' \boldsymbol{\beta}, \sigma_i^2 = e^{z_i' \boldsymbol{\gamma}} \quad (17)$$

where $E(Y_i) = \mu_i$, $E(\epsilon_i) = 0$, and $\text{Var}(\epsilon_i) = \sigma_i^2$. $\boldsymbol{\beta}$ is the collection of location effects and $\boldsymbol{\gamma}$ represents the dispersion effects. We must determine which columns are to be included in the location model and which are to be included in the dispersion model. Often, we want to initially consider all location effects that can be estimated. In this case, we may use a half-normal probability plot of the location effect estimates (see **Half-Normal Plot**) or Lenth's method (see **Lenth's Method for the Analysis of Unreplicated Experiments**). The next two sections describe the different approaches for replicated and unreplicated experiments.

Location and Dispersion Effects in Replicated Experiments. Suppose that in the previously discussed resistivity example, each of the 16 factor combinations (treatments) in Table 3 was repeated m times, resulting in m observations for each row. This is called a *replicated experiment* in that each combination is repeated (replicated) multiple times. Accordingly, in run i of the experiment, we can calculate the sample mean $\bar{y}_i = \sum_{j=1}^m y_{ij} m^{-1}$ and variance $s_i^2 = (m-1)^{-1} \sum_{j=1}^m (y_{ij} - \bar{y})^2$. In the LM framework one may choose to model s_i or $\log(s_i^2)$ using the square root or log transformation respectively for investigating dispersion effects. Alternatively, we can model the s_i^2 's using a GLM with an appropriate distribution and link function and identify and estimate dispersion effects. These dispersion effects may then be used in the estimation of the location effects.

For example, assume the response is normally distributed with $\mathbf{Y} \sim \mathbf{N}(\boldsymbol{\mu}, \mathbf{V})$ where $\mathbf{V} = \text{diag}(\sigma_i^2)$. Then $(m-1)s_i^2\sigma_i^{-2}$ has a gamma distribution. We could use a GLM with a gamma distribution and, say, a log link to analyze the sample variances. If all columns in $\mathbf{X}$ are candidates, we can use Lenth's method (see **Lenth's Method for the Analysis of Unreplicated Experiments**) to determine which are considered active. We then save the fitted values, $\hat{\sigma}_i^2$ from the variance model and form the matrix $\hat{\mathbf{V}} = \text{diag}(\hat{\sigma}_i^2)$. Lastly, we can perform weighted least-squares (WLS) analysis to estimate the location effects. In WLS, we estimate the location effects as

$$\mathbf{b}_w = (\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{Y} \quad (18)$$

(See Kutner *et al.* [4] for details on WLS estimation.) The implementation of this two-step procedure is relatively straightforward so we next discuss location and dispersion effect estimation with unreplicated data.

Location and Dispersion Effects in Unreplicated Experiments. It is much more difficult to study dispersion effects in unreplicated experiments. Generally, we need to *identify* location and dispersion effects before using GLM models for estimation and testing. Again, location effect identification techniques described in **Half-Normal Plot** and **Lenth's Method for the Analysis of Unreplicated Experiments** may be used. For information on dispersion effect identification in unreplicated designs under the LM framework, see **Bergman-Hynén Method for**

Dispersion Effects; Box-Meyer Method for Dispersion Effects; Harvey's Method for Dispersion Effects, and McGrath and Lin [5] for examples. We will outline a GLM approach that shares much in common with the work of Lee and Nelder [6], Engel and Huele [7], and Pan and Taam [8] as outlined in [3, pp. 294–297].

With replication, we first estimated the variances and then used these as weights in the procedure for estimating the means. However, without replication we have no estimate of variance at each run and therefore have no initial weights. So we first fit the model for the means without weights and store the residuals. The squared residuals then become the response for the variance model. The fitted values of the variance model are stored and their reciprocals become the weights for estimating the means. Residuals are again calculated and the process is reiterated until the parameters converge.

We list the specific steps in the procedure when we assume a normal model with identity link for the location model and a gamma distribution with a log link for the dispersion model. These steps are easily generalized to other distributions and links. This method is called the *double GLM approach*.

1. Obtain the initial location effect estimates, $\mathbf{b}^{(0)}$ by using OLS.
2. Calculate the residuals (e_i) from step 1, or later, step 4.
3. Letting e_i^2 be the responses for a GLM with a gamma distribution and a log link, find the dispersion effect estimates $\boldsymbol{\gamma}^{(0)}$ and the estimated variances, $\hat{\sigma}_i^{2(0)}$.
4. Perform WLS estimation of the means by substituting $\hat{\mathbf{V}}_0 = \text{diag}(\hat{\sigma}_i^2)$ for $\mathbf{V}$ in (18). Call the new location effect estimates $\mathbf{b}^{(1)}$.
5. Repeat steps 2–4 until the parameters converge.

The above procedure is based on MLE. Unfortunately, the variance estimates from this method are biased as no adjustment is made for the loss of **degrees of freedom** from estimating the mean model. These underestimations lead to **bias** in the standard errors for the location effect estimates. A method that makes an adjustment for this loss of degrees of freedom is called *restricted maximum-likelihood estimation* (REML). From a practical point of view, the only change to the MLE procedure above is that instead of using e_i^2 as the response in step 3, we

use $e_i^2 + h_{ii}\hat{\sigma}_i^2$ where h_{ii} is the i th diagonal term of $\mathbf{H} = \hat{\mathbf{V}}^{-1/2}\mathbf{X}(\mathbf{X}'\hat{\mathbf{V}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\hat{\mathbf{V}}^{-1/2}$ (see [7] and [[3], pp. 296–297]).

As an example of using GLMs to estimate location and dispersion effects in unreplicated designs, we study a welding example previously discussed by many (see [8] and references therein). Nine factors are studied in a 2^{9-5} design as shown in Table 3 with the response of weld strength in the y_2 column. In row 2^{9-5} of Table 3, we use the factor labeling of [8]. From the half-normal probability plot of the 15 location effect estimates (not shown), it is clear that the largest location effects by far are B and C . Assuming these constitute the location model, the Bergman and Hynén method finds significant dispersion effects H , J , and C . We run the double GLM REML procedure described above and obtain the results given in Table 5.

It is clear from this output that the main effects of B and C are significant, as expected from the **half-normal plot**. However, while the Bergman and Hynén method found the three dispersion effects C , H , and J to be active, the double GLM method indicates that H is not active. This dataset exemplifies the difficulty of estimating location and dispersion effects in unreplicated experiments. Indeed, different authors suggest different models for this example (see [6, 7], and [8]). Even different algorithms for finding the REML estimates may give varying results. (The output in Table 5 was obtained by running the dglm script in S-plus 6.1.) While more research is needed in this area, it is clear that GLMs are useful for attacking this difficult problem.

Summary

GLMs can be viewed as an extension of standard regression models where the distributional assumptions are broadened from the normal distribution to members of the exponential family. This allows, for example, count data to be modeled by a more natural distribution such as the binomial or Poisson instead of transforming the data to achieve near normality. The same can be accomplished for continuous data by using, for example, the gamma distribution.

In the interest of brevity, we have left out many details of generalized linear modeling. We encourage those interested in the more theoretical aspects to consult [2]. For more details on applications in the quality and engineering areas, see [3].

While GLMs have become somewhat common in the biological sciences, for example, they are slowly being recognized as useful models in engineering and quality and reliability studies. We hope that our discussion of uses in fractional **factorial** designs will encourage further use.

RICHARD N. MCGRATH

Harvey's Method for Dispersion Effects

Introduction

Estimation of location and **dispersion effects** is typically done through replicated experiments (see [1–3]), but due to the cost of such experiments there has been much interest in developing methods for identification and estimation of these effects in unreplicated experiments. A similar problem for identifying just location effects in unreplicated designs has been studied extensively and a review of the various methods is summarized in [4]. Several methods have been proposed for studying dispersion effects from unreplicated (fractional) **factorial** designs [5–8].

The problem of identifying location and dispersion effects from unreplicated 2^{k-p} designs is difficult and relies on the affect sparsity principle given that the number of runs is $N = 2^{k-p}$ while the potential number of parameters is $2N$. However, even under the effect sparsity principle, Pan [9] and McGrath and Lin [10] discuss the problem of misidentification of the location and the impact on inference for dispersion effects. In addition, under the assumption that the location model is correctly identified, the presence of multiple dispersion effects can greatly influence the dispersion analysis (see [8]). It is also shown in [8] that all noniterative methods exhibit biases that depend on the fitted location model and active dispersion effects (parameters other than the one being estimated) and therefore can be large. This **bias** can lead to spurious identification of effects as well as underestimation or overestimation of real effects.

This article takes a look at the two-step approach proposed in [8] which incorporates a noniterative identification step followed by an iterative final estimation step. The noniterative step is a modification of Harvey's method (see [11]) and the iterative step is restricted maximum likelihood (REML). This two-step approach eliminates some of the bias present in the noniterative methods.

Notation, Model, and Methods

This section provides the notation that will be used throughout along with the assumed dispersion model

and a description of the two-step modified Harvey (MH) and REML estimation scheme. Throughout we consider only two-level (fractional) factorial designs along with the key assumption that the true location model $\mathcal{L}$ is correctly identified during the initial location-modeling stage. The misidentification of the location model can lead to confounding of location and dispersion effects, as discussed in [9, 10].

Notation

The following notation will be used throughout:

1. $X = [X_0 | \cdots | X_m]$ denotes an $N \times (m+1)$ design matrix corresponding to a 2^{k-p} fractional design with $N = 2^{k-p}$.
2. X_0 is the first column of X and is a vector of $+1$ s; for $j \geq 1$, X_j is the vector of $+1$ s and -1 s corresponding to the high and low levels of factor j .
3. x_i denotes the i th row of X .
4. $S(j+) = \{i : X_{i,j} = +1\}$, where $X_{i,j}$ is the i th element of X_j . Similarly, $S(j-) = \{i : X_{i,j} = -1\}$. In addition, $S(j_1+, j_2+) = \{i : X_{i,j_1} = +1, X_{i,j_2} = +1\}$; similarly for $S(j_1+, j_2-)$, $S(j_1-, j_2+)$, and $S(j_1-, j_2-)$. This notation can be generalized to $S(j_1\pm, \dots, j_m\pm) = \{i : X_{i,j_1} = \pm 1, \dots, X_{i,j_m} = \pm 1\}$.
5. For $j_1, j_2, j_3 \in \{1, 2, \dots, N\}$, we write $j_1 = j_2 \circ j_3$ if X_{j_1} can be obtained by elementwise multiplication of X_{j_2} and X_{j_3} . For example, the interaction term $AB = A \circ B$.
6. Let $\mathcal{L} = \{0\} \cup \{l_1, \dots, l_q\}$ represent the set of active location effects and let $\mathcal{D} = \{0\} \cup \{d_1, \dots, d_r\}$ represent the set of active dispersion effects. Letters such as A , B , and so forth will be used interchangeably with l_j and d_j . Both 0 and I denote the intercept.
7. A set $\mathcal{S}$ is closed if it is closed under the $\circ$ operation. The closure of a set $\mathcal{S}$ is denoted by $\overline{\mathcal{S}}$. Given a set $\mathcal{S}$, define the set $\mathcal{S}_{-j} = \mathcal{S} - \{j\}$.
8. $(r_1, \dots, r_N)'$ denotes the vector of **residuals** from a fitted location model.

Models

We begin with the model for the replicated case. Suppose the data, possibly after a suitable transformation, follow the location-scale model

$$Y_{ir} = \mu_i + \sigma_i \varepsilon_{ir}, \quad i = 1, \dots, N, \quad r = 1, \dots, R \quad (1)$$

2 Harvey's Method for Dispersion Effects

where R represents the number of replications of each design point and ε_{ir} are independent and identically distributed (i.i.d.) with mean 0 and variance 1. A structural model relates the mean, μ_i , to the location effects, β_j , and the variances, σ_i^2 , to the dispersion effects, ϕ_j , through link functions $g(\cdot)$ and $h(\cdot)$, $g(\mu) = X\beta$, $h(\sigma^2) = X\phi$. The linear link function is the most common one for the mean and for the variance we will consider the multiplicative or log-linear model

$$\sigma_i^2 = \exp(x_i' \phi), i = 1, \dots, N \quad (2)$$

A linear dispersion model is also considered in [8] where they provide modeling strategies for that case. The log-linear dispersion model is used most frequently since it does not require constraints on the parameters to ensure the estimates of σ_i^2 are positive.

With replicated data, the location and dispersion analysis can be based on the mean $\bar{Y}_i$ and sample variance S_i^2 of the replications at each design run. For dispersion effects, one can fit an appropriate model to the sample variances and estimate the dispersion effects ϕ_j . A linear analysis of the sample variances is discussed in [12, 13] for random-effects and variance-components models. The idea of doing the log-linear analysis of sample variances goes back to Bartlett and Kendall (see [1]). See [3] for a comparison of the properties of this estimation method with other methods including the maximum likelihood (ML).

We will now look at the case of interest with no replications, that is model (1) with $R = 1$. The method that we will focus on is the two-step approach proposed in [8] which incorporates a noniterative identification step followed by an iterative final estimation step. The noniterative step is a modification of Harvey's method [11] and the iterative step is REML.

Methods

Harvey's Method. With a log-linear dispersion model the most natural extension of Bartlett and Kendall's (see [1]) idea applied to the unreplicated case is to do a log-linear analysis of the squared residuals instead of the sample variances. That is, we fit a log-linear model

$$\log r_i^2 = x_i' \phi + u_i \quad (3)$$

and estimate the dispersion effects ϕ_j through **least squares**. Harvey [11] studied this method in the

general regression context. See also [14] for results about modeling functions of residuals for doing variance estimation. We refer to this method as Harvey's method (H method).

For a 2^{k-p} design, the estimate of ϕ_j from the H method can be written as

$$\begin{aligned} D_j^H &= \frac{1}{N} \left(\sum_{S(j+)} \log r_i^2 - \sum_{S(j-)} \log r_i^2 \right) \\ &= \log \left(\frac{\prod_{S(j+)} r_i^2}{\prod_{S(j-)} r_i^2} \right) \end{aligned} \quad (4)$$

It is shown in [3] that for the replicated case, where the sample variances are used instead of the squared residuals, D_j^H in equation (4) is the ML under a fully saturated dispersion model and is recommended in the initial model-identification stage. It is pointed out in [8] that this method, along with the methods of [5–7] are all biased in the context of multiple active dispersion effects. The amount of bias depends on the fitted location model along with the active dispersion effects. However, unlike the other methods, the size of the bias of the H method decreases as the run size increases.

Modified Harvey Method. A modification to the H method is proposed in [8] to decrease the bias of the H method. This modified method (MH method) is obtained by applying the H method to the modified residuals from an expanded location model discussed in [7]. The idea is that we first estimate a location model through least squares and identify the location model $\mathcal{L}$. For each dispersion effect j , let $\mathcal{L}_j^E$ be the expanded location model, which is the union of $\mathcal{L}$, $\{j\}$, and all interactions between j and the elements of $\mathcal{L}$. For example, if $\mathcal{L} = \{I, A, B\}$ and $j = C$, then $\mathcal{L}_j^E = \{I, A, B, C, AC, BC\}$. If we let $\{\tilde{r}_i, i = 1, \dots, N\}$ denote the residuals from the expanded location model, then the MH estimator is

$$D_j^{MH} = \frac{1}{N} \left(\sum_{S(j+)} \log \tilde{r}_i^2 - \sum_{S(j-)} \log \tilde{r}_i^2 \right) \quad (5)$$

Iterative Methods. Once a tentative model for location and dispersion effects has been identified,

one can use iterative methods to refine the model and estimate the parameters more efficiently. One approach is to use the full ML for location and dispersion effects under normal theory (e.g., see [11]) or under **generalized linear models** (see [15–17]). Another approach is to use a log-linear model to estimate the dispersion effects (as in the H or MH method) and then iterate, using iteratively reweighted least squares (IRLS), to refit the location model at each step. Both approaches are discussed in [18], but they do not discuss model-selection issues. Lee and Nelder [19] developed REML for dispersion analysis that takes into account the loss of **degrees of freedom** from location model estimation. Iterative methods are considered later in the context of the proposed modeling strategy from [8] where they show that the bias is reduced even further through the use of REML at the final estimation stage.

Properties of the H and MH Methods

Properties of the H Method

For replicated studies, it is shown in [3] that the original Bartlett–Kendall method is unbiased. However, in unreplicated 2^{k-p} experiments the corresponding H method is biased, and the bias is related to the structure of the active dispersion effects as well as the fitted location model (see [8]). The main result is for the case when the location model is closed.

Proposition 1. Suppose $\mathcal{L} = \overline{\mathcal{L}}$ with $\dim(\mathcal{L}) \leq N/2$. Then D_j^H is unbiased if $j \notin \overline{\mathcal{D} - \mathcal{L}}$.

Let us take a look at some special cases of the proposition: (a) If $\mathcal{D} \subset \mathcal{L}$, then the estimators of all the active dispersion effects are unbiased. (b) Let $\mathcal{L} = \{I, A\}$ and $\mathcal{D} = \{I, d\}$. If $d = A$, then D_j^H is unbiased for all j . If $d \neq A$, then D_j^H is biased for $j = d$ and unbiased for others.

An example will also illustrate the point of the bias present in the H method. Consider the case where $\mathcal{L} = \{I, A\}$ and we want to determine if factor A has a dispersion effect. If $\mathcal{D} = \{I, A\}$, then D_A^H is unbiased. But if $\mathcal{D} = \{I, A, B, AB = C\}$ then D_A^H is biased. Figure 1(a) shows the distribution of D_A^H when $\phi_A = 1, \phi_B = -1.67$, and $\phi_{AB} = 1.67$. Note that the distribution of D_A^H is centered at 0 even though factor A has an active dispersion effect. So in the presence of active dispersion effects for B and AB (or its aliased **main effect** C), one can miss an active dispersion effect for A . Similarly, if $\phi_A = 0$ instead of $\phi_A = 1$, then the distribution of D_A^H would be centered at -1 , and a spurious dispersion effect for A may occur when B and AB have active dispersion effects.

Properties of the MH Method

The MH method removes some of the bias present in the H method. For example, when $\mathcal{L} = \{I\}$ and $\mathcal{D} = \{I, A\}$ we know from Proposition 1 that D_A^H is biased. However, by purposefully fitting

Figure 1 Distribution of noniterative and iterative estimators of ϕ_A . From the example where $\phi_A = 1, \phi_B = -1.67$, and $\phi_{AB} = 1.67, N = 2^2$: (a) distribution of D_A^H (D_A^{MH}); (b) distribution of the ML estimate of ϕ_A [© American Statistical Association, 2001.]

the expanded location model $\mathcal{L}_A^E = \{I, A\}$, then by Proposition 1, D_A^H is unbiased. This is the motivation for the MH method. Now the MH method is not free from bias altogether since it can coincide with the H method in some cases.

By Proposition 1, if $\mathcal{L}_A^E$ is closed with $\dim(\mathcal{L}_k^E) \leq N/2$ and $\mathcal{D} \subset \mathcal{L}_j^E$, then D_j^{MH} is unbiased. The following characterization of other situations where D_j^{MH} is unbiased is also given in [8].

Proposition 2. Let $\mathcal{D}$ be the set of active dispersion effects. If $j \notin \overline{\mathcal{D}}_{-j}$, then D_j^{MH} is unbiased.

Brenneman and Nair [8] also show that the bias diminishes as $N \rightarrow \infty$ for both the H and MH methods, so the methods are not structurally flawed. They also obtain a lower bound for the variance of D_j^{MH} under normality as $V(D_j^{\text{MH}}) \geq V(\log \chi_1^2)/N \approx 4.93/N$. This can then be used to obtain liberal tests for active effects in the model-selection strategy.

Properties of Iterative Method (ML and REML)

Through simulation studies, it is shown in [8] that the bias present in the H and MH methods can be reduced through ML and REML. As a simple example, we can revisit the case when $\mathcal{L} = \{I, A\}$, $\mathcal{D} = \{I, A, B, AB = C\}$ and we want to determine if factor A has a dispersion effect. Recall that Figure 1(a) shows the distribution of D_A^H ($= D_A^{\text{MH}}$, in this case) when $\phi_A = 1$, $\phi_B = -1.67$, and $\phi_{AB} = 1.67$. Since the center of the distribution of D_A^H is at 0, we would in most instances miss this effect. However, if we keep A in the dispersion model along with B and AB then we see in Figure 1(b) that the distribution of $\hat{\phi}_A$ from ML (similarly for REML) is centered at 1. Thus by placing interactions of identified dispersion effects from the MH method in the initial dispersion model and then performing an iterative estimation method on this model, one can correct for the bias of the MH method.

Modeling Strategy

The H method would be the most natural approach under the assumption of a log-linear model for dispersion. However, since one first has to estimate and remove location effects, this can lead to biased dispersion estimates. Part of the bias problem is due to the lack of balance in the location model in relation to the

dispersion effect being estimated. The lack of balance is addressed by the MH method which expands the location model so that the dispersion effect of interest, as well as all of its interactions with active location effects, are estimated. This induces the balance in the estimated residuals, as originally observed in [7], and reduces the underestimation phenomenon. A second problem is the biased estimation of ϕ_A when dispersion effects of B and AB are active. This can lead to: (a) the spurious identification of inert effect A or (b) missing the active effect A . In order to take care of these problems, the proposed strategy in [8] is to initially choose a possibly larger model for dispersion effects $\mathcal{D}^{\text{init}}$ and then use an iterative method, REML, to eliminate spurious effects or pick up active effects. Their strategy is outlined below:

1. Fit a location model using ordinary least squares (OLS) and identify the location model $\mathcal{L}$.
2. If $\mathcal{L}$ contains a closed set $\mathcal{L}'$ with $\dim(\mathcal{L}') \geq N/2$, then identification of dispersion effects is *a priori* difficult and additional experimentation is necessary.
3. If not, then use the MH method to estimate dispersion effects and use an appropriate method to determine the active effects.
4. For a dispersion effect j that is identified as inert, include j in $\mathcal{D}^{\text{init}}$ (the initially selected dispersion model) if there are active effects d_1 and d_2 such that $j = d_1 \circ d_2$.
5. Using $\mathcal{L}$ and $\mathcal{D}^{\text{init}}$ as the identified location and dispersion models, estimate the effects for these models by REML. Discard any dispersion effects that are now identified as inert and refit the submodel using REML.

One can use half-normal plots or more formal methods found in [4] to detect active location effects in the initial model-selection stage. For more formal inference in the final stage, one can rely on parametric **bootstrap** techniques.

Example

This section contains a simulated data set from [8] that illustrates the modeling strategy. Consider the data in Table 1 generated from a 2^4 design in which $\mathcal{L} = \{I, A, B\}$ and $\mathcal{D} = \{I, A, C\}$. The true values of the parameters are $\beta_A = 6$, $\beta_B = 5$, $\phi_A = 2$, and $\phi_C = 1.5$. The half-normal plots for

Table 1 Simulated 2^4 design dataset for which models $\mathcal{L} = \{I, A, B\}$ and $\mathcal{D}^{\text{init}} = \{I, A, C, AC\}$; $\beta_A = 6$, $\beta_B = 5$, $\phi_A = 2$, and $\phi_C = 1.5^{(a)}$

identifying location and dispersion effects are given in Figure 2. From the plot of location effects, it is clear that the only active location effects are A and B with estimates of 5.83 and 5.96, respectively. The plot of dispersion effects using the MH method shows that A , C , and AC are initially identified as being active with estimates of 2.78, 2.34, and 1.60, respectively. The MH method's approximate critical

value for $\alpha = 0.05$ is $1.96 \times \sqrt{4.93/16} = 1.09$, so $\mathcal{D}^{\text{init}} = \{I, A, C, AC\}$. Note that if only factors A and C would have been identified as active, we would still add their interaction, factor AC , to the initially identified dispersion model prior to REML.

The next step is to use REML estimation with the identified models $\mathcal{L} = \{I, A, B\}$ and $\mathcal{D}^{\text{init}} = \{I, A, C, AC\}$. The estimates are $\hat{\beta}_A = 6.04$, $\hat{\beta}_B = 5.14$ for location effects and $\hat{\phi}_A = 2.60$, $\hat{\phi}_C = 1.38$, and $\hat{\phi}_{AC} = 0.16$ for dispersion effects. The estimates for dispersion factors A and C did not change much but the estimate for factor AC changed dramatically from 1.60 to 0.16. This indicates that AC may have been picked up spuriously by the MH method during the initial modeling stage.

For more formal inference about AC , one can use parametric bootstrap under normal error structure. The resulting 95% bootstrap **confidence intervals** are: factor $A - (1.69, 3.71)$, factor $C - (-0.01, 2.52)$, factor $AC - (-1.00, 1.55)$. This provides evidence that AC was spuriously picked up by the MH method. After AC is removed, the REML estimates are practically identical to the initial estimates while the final 95% bootstrap confidence intervals are factor $A - (1.71, 3.66)$ and factor $C - (0.47, 2.52)$. The final conclusion is that factors A and C are significant dispersion effects while factor AC is not.

Figure 2 Half-normal plots of location and dispersion effects for simulated dataset in which $\mathcal{L} = \{I, A, B\}$ and $\mathcal{D}^{\text{init}} = \{I, A, C, AC\}$; $\beta_A = 6$, $\beta_B = 5$, $\phi_A = 2$, and $\phi_C = 1.5$. The dashed line in the plot of dispersion-effect estimates is the approximate critical value for the MH method [© American Statistical Association, 2001.]

Weaknesses of Technique

There are two main weaknesses to the strategy of identification and estimation of dispersion effects presented here. The first weakness is that the MH method requires fitting a new location model for each dispersion-effect estimate. For example, in the $2^4 = 16$ -run experiment in the previous section, we had to fit 15 different location models in order to get the 15 MH estimates. This can be very time consuming. The second weakness is that there is a problem when one of the residuals turns out to be identically 0, where $\log(0)$ is undefined, or close enough to 0 for the computer to have trouble taking the logarithm. An *ad hoc* fix to this problem is provided in [20] where they propose replacing $r_i = 0$ with $0.5 \times \min\{|r_j| : j \text{ with } r_j \neq 0\}$. While this provides a way to get MH estimates, the properties of this type of substitution have not been studied. And finally, a third weakness, related to the second weakness, is when a residual that is exactly 0 is computed as a very small "machine zero" number. In this case the program would not have trouble computing the logarithm but the user would not be aware that a problem has occurred.

Conclusion

All noniterative methods (e.g., [5–7]) exhibit biases that depend on the fitted location model and active dispersion effects (parameters other than the one being estimated) and therefore can be large. This bias can lead to spurious identification of effects as well as underestimation or overestimation of real effects. The two-step approach proposed in [8], which incorporates the noniterative MH method identification step followed by an iterative REML final estimation step, eliminates some of the bias present in the noniterative methods.

Ridge Analysis in Experimental Design

Fitting a Response Surface to Data

Suppose an experimenter wishes to examine several predictor variables $x_1, x_2, \dots, x_k$ in order to determine their effects, individual and combined, on a response variable y . A standard way of proceeding is to decide on n (say) specific combinations of levels $(x_{1u}, x_{2u}, \dots, x_{ku})$, $u = 1, 2, \dots, n$, at each of which the value of the response y , y_u for the u th experiment, will be measured. These n experiments, or *runs* as they are usually called, form the *experimental design* or simply the *design*. Further analysis of the experimental results arising from performing the design can consist of fitting a model, often of polynomial form, to the data, using the least-squares method of regression analysis, and then assessing what the computations reveal. The fitted model could be first order (planar), for example, $\hat{y} = b_0 + b_1x_1 + b_2x_2 + \dots + b_kx_k$, where each of the x 's enters only to first order (power 1); or could be second order (quadratic) of the form (1), where all possible second-order terms (power 2, squares and cross-products) are included.

$$\begin{aligned} \hat{y} = & b_0 + b_1x_1 + b_2x_2 + \dots + b_kx_k \\ & + b_{11}x_1^2 + b_{22}x_2^2 + \dots + b_{kk}x_k^2 + b_{12}x_1x_2 \\ & + b_{13}x_1x_3 + \dots + b_{k-1,k}x_{k-1}x_k \end{aligned} \quad (1)$$

The *hat* (caret) over the y indicates the *predicted value* of y . The b 's are numbers, estimates obtained via the least-squares method, of the *true but unknown* regression coefficients. We assume here that appropriate statistical tests have been carried out to determine that the chosen fitted model is *adequate* to express the main features of the response data and does not suffer from *lack of fit*.

If a second-order surface seems useful and explains the data well, further analysis could take several forms such as viewing two- or three-dimensional surface or sectional plots, performing canonical reduction (a technique that determines the principal features of the surface), or performing *ridge analysis*, the topic of this article. Because ridge analysis does not require one to be able to view the fitted regression surface as a whole, it may be applied even when it is difficult to draw or visualize the surface, for

example, in four or more dimensions of the predictor variable space. The starting point can be *any* selected point in the experimental space; we shall designate it by $\mathbf{f} = (f_1, f_2, \dots, f_k)'$, and call it the *focus*. In many cases, the focus might simply be the coded origin $\mathbf{f} = \mathbf{0}$, the center of the experimental region. Higher, lower, or intermediate local optima values of the response can be specified as desirable for the ridge analysis. The calculation of the coordinates of a ridge trace path also helps one to assess the typically complex interplay between the input variables as the response improves. Use of this tool can supplement, or replace, the canonical reduction of a second-order surface. We explain below how the various paths can be distinguished.

Ridge Analysis for Examining Second-Order Fitted Models, Unrestricted Case, General Focus $\mathbf{f}$

Suppose, in the x space where we have fitted a second-order response function, we (mentally) construct a sphere of radius R about the selected focus $\mathbf{f}$. Somewhere on that sphere there will be a point with the highest response value. As the radius R is changed, all such highest response points will mark out a locus, or path, moving outward from the focus. Similarly, there will also be a path of lowest response. If we extend this idea to points on the spheres where the response is stationary, that is, a minimum or maximum *locally but NOT globally*, more paths will come to light. In fact, there are always $2k$ such paths. Usually, but not always, only the paths that provide the maximum response and the minimum response are likely to be interesting to the experimenter. For that reason, these two paths tend to receive the most emphasis. However, secondary paths could well be of interest in certain practical situations; for example, they might provide good, though not optimum, response values at lower cost or with fewer impurities. As we shall see, we shall always know which of the $2k$ paths we are on.

The basic ridge analysis method is as follows. The fitted second-order surface of equation (1) can be written in matrix form as

$$\hat{y} = b_0 + \mathbf{x}'\mathbf{b} + \mathbf{x}'\mathbf{B}\mathbf{x} \quad (2)$$

2 Ridge Analysis in Experimental Design

where $\mathbf{x}' = (x_1, x_2, \dots, x_k)$, $\mathbf{b}' = (b_1, b_2, \dots, b_k)$, and where

$$\mathbf{B} = \begin{bmatrix} b_{11} & \frac{1}{2}b_{12} & \dots & \frac{1}{2}b_{1k} \\ \dots & b_{22} & \dots & \frac{1}{2}b_{2k} \\ \dots & \dots & \dots & \dots \\ \text{sym} & \dots & \dots & b_{kk} \end{bmatrix} \quad (3)$$

is a symmetric matrix containing all second-order coefficients. Note the off-diagonal halves; it is easy to forget them! We seek the stationary (or “turning”) values of equation (2) subject to being on a sphere, radius R , centered at the focus $\mathbf{f} = (f_1, f_2, \dots, f_k)'$, with equation

$$(\mathbf{x} - \mathbf{f})'(\mathbf{x} - \mathbf{f}) = R^2 \quad (4)$$

We consider the Lagrangian function

$$G = b_0 + \mathbf{x}'\mathbf{b} + \mathbf{x}'\mathbf{B}\mathbf{x} - \lambda\{(\mathbf{x} - \mathbf{f})'(\mathbf{x} - \mathbf{f}) - R^2\} \quad (5)$$

where λ is a Lagrangian multiplier. (For the method of “Lagrange’s undetermined multipliers”, see [1], pp. 231–233.) Differentiation with respect to $\mathbf{x}'$ leads to

$$\frac{\partial G}{\partial \mathbf{x}'} = \mathbf{b} + 2\mathbf{B}\mathbf{x} - 2\lambda(\mathbf{x} - \mathbf{f}) \quad (6)$$

and setting equation (6) equal to a zero vector implies that

$$2(\mathbf{B} - \lambda\mathbf{I})\mathbf{x} = -\mathbf{b} - 2\lambda\mathbf{f} \quad (7)$$

For many given values of λ (the specific choices will be discussed below) we can write a solution for $\mathbf{x}$ as

$$\mathbf{x} = -\frac{1}{2}(\mathbf{B} - \lambda\mathbf{I})^{-1}(\mathbf{b} + 2\lambda\mathbf{f}) \quad (8)$$

This leads us into the following solution sequence:

1. Choose a value of λ appropriate for the desired path (to be explained below).
2. Obtain $\mathbf{x}$ from equation (8).
3. Using that $\mathbf{x}$
 - (a) Evaluate $R^2 = (\mathbf{x} - \mathbf{f})'(\mathbf{x} - \mathbf{f})$ and so obtain R .
 - (b) Evaluate $\hat{y} = b_0 + \mathbf{x}'\mathbf{b} + \mathbf{x}'\mathbf{B}\mathbf{x}$.
 - (c) Tabulate $\mathbf{x}$, R , and $\hat{y}$.

Then the point $\mathbf{x}$ will be on the desired path of stationary values and will lie on a sphere of radius R centered at $\mathbf{f}$.

Distinguishing between the Various Paths

There are, theoretically, $2k$ possible stationary paths. How do we know, when we pick a λ value, on which of these paths we have determined a point? The key lies in the k eigenvalues of $\mathbf{B}$, namely, the values that result from solving $\det(\mathbf{B} - \lambda\mathbf{I}) = 0$, a routine computer calculation. These eigenvalues of $\mathbf{B}$ will be denoted here by $\mu_1, \mu_2, \dots, \mu_k$. In using this notation, we shall assume that they are ordered from most negative to most positive, that is, in ascending order with regard to sign. Words like *lower* and *higher*, or *up* and *down*, are always used in that sense here.

The theory in [2] tells us that, if we select values of λ from $+\infty$ downwards as far as the highest eigenvalue μ_k , we shall always be on the “maximum $\hat{y}$ ” path. Similarly, values of λ from $-\infty$ upwards to the lowest eigenvalue μ_1 put us on the “minimum $\hat{y}$ ” path. Intermediate paths lie in the ranges of λ between the eigenvalues of $\mathbf{B}$. When λ is $+\infty$ or $-\infty$, the value of R is zero and we are at the focus $\mathbf{f}$. As we move λ back down from $+\infty$ to the largest eigenvalue μ_k of $\mathbf{B}$, R rises to ∞ . As we move λ forward from $-\infty$ to the smallest eigenvalue μ_1 of $\mathbf{B}$, R again rises to ∞ . In between each successive pair of eigenvalues, R falls from ∞ to some value above zero and rises again to ∞ , each “loop” corresponding to *two* paths of stationary values of $\hat{y}$. This means that there are $2k$ ridge paths in all, some of which may not appear at the low R values that are usually of most practical interest. So,

1. choosing $\lambda > \mu_k$ provides a locus of maximum $\hat{y}$ as R changes;
2. choosing $\lambda < \mu_1$ provides a locus of minimum $\hat{y}$ as R changes; and
3. choosing $\mu_1 < \lambda < \mu_k$ gives intermediate stationary values.

Note that we do not actually need the eigenvalues of $\mathbf{B}$ to obtain the paths, but only to distinguish between paths. For the loci of the maximum $\hat{y}$ and the minimum $\hat{y}$ which are the most common applications, the eigenvalues are really not needed, because choosing λ values decreasing from ∞ gives the path of maximum $\hat{y}$ while using values increasing from $-\infty$ gives the path of minimum $\hat{y}$. However, obtaining the actual eigenvalues is recommended, simply to avoid the possibility of mistakenly getting onto an unwanted path. When $\lambda = 0$, equation (8)

becomes $\mathbf{x} = -\frac{1}{2}\mathbf{B}^{-1}\mathbf{b}$, which defines the overall stationary point of the second-order surface (e.g., the center of the system if the contours are all ellipsoidal ones). Note that this stationary point could be on *any* of the paths, depending on where zero fits into the listing of the eigenvalues of $\mathbf{B}$.

Applying the Above Results to a First-Order Model as a Special Case

The first-order model $\hat{y} = b_0 + b_1x_1 + b_2x_2 + \cdots + b_qx_k$ occurs when $\mathbf{B} = \mathbf{0}$. The “eigenvalues of $\mathbf{B}$ ” are thus all zero, and there are only two segments for λ , $-\infty$ to 0, and 0 to $+\infty$. The solution for $\mathbf{x}$ reduces to

$$\mathbf{x} = \mathbf{f} + (2\lambda)^{-1}\mathbf{b} \quad (9)$$

Choosing λ in the range $[0, \infty]$, that is, positive, gives the straight-line steepest-ascent direction, and choosing λ negative in the range $[-\infty, 0]$ gives the straight-line steepest-descent direction. Note that $\mathbf{x} - \mathbf{f}$ is proportional to $\mathbf{b}$, as it should be.

Behavior of the Ridge Paths in General

The $\hat{y}$ values on a ridge path will always exhibit one of the following four behaviors. The response will

1. decrease monotonically, or
2. increase monotonically, or
3. pass through a maximum and then decrease monotonically, or
4. pass through a minimum and then increase monotonically.

In cases 3 and 4, the path changes slope as it passes through the stationary point of the second-order **response surface** at the value $\lambda = 0$. The path that contains the stationary point is determined by the position of $\lambda = 0$ in relation to the eigenvalues of $\mathbf{B}$, as mentioned above.

Worked Example for a Three-Predictor Response Surface

A specific example of a second-order fit was discussed elsewhere in this encyclopedia (*see* **Central**

Composite Designs). The surface was fitted to 16 observations and took the form

$$\begin{aligned} \hat{y} = & 57.31 + 1.50x_1 - 2.13x_2 + 1.81x_3 - 4.69x_1^2 \\ & - 6.27x_2^2 - 5.21x_3^2 - 7.13x_1x_2 \\ & - 3.27x_1x_3 - 2.73x_2x_3 \end{aligned} \quad (10)$$

A **blocking** coefficient ($1.29x_B$) also appeared in the original equation, but it has been omitted here because it plays no role in the ridge analysis to follow. In terms of the notation used earlier, $b_0 = 57.31$,

$$\begin{aligned} \mathbf{b} &= \begin{bmatrix} 1.50 \\ -2.13 \\ 1.81 \end{bmatrix}, \text{ and} \\ \mathbf{B} &= \begin{bmatrix} -4.69 & -3.565 & -1.635 \\ -3.565 & -6.27 & -1.365 \\ -1.635 & -1.365 & -5.21 \end{bmatrix} \end{aligned} \quad (11)$$

The eigenvalues of $\mathbf{B}$ are -10.04 , -4.37 , and -1.77 , all negative. Thus, to follow the path of maximum response for example, we substitute values of λ between $+\infty$ and -1.77 in equation (8). (To approximate ∞ in computations, we use $\lambda = 1000$ or some other large number. This provides a check on the calculations since the solution should be very close to $\mathbf{x} = \mathbf{f}$, with R very close to zero.) Selected λ values for our example are shown in Table 1 together with the corresponding results of applying the solution sequence below equation (8), using a Minitab subroutine/macro [3, Chapter 12]. We see that the stationary point, defined by setting $\lambda = 0$, where a maximum $\hat{y} = 58.29$ is predicted, lies on this maximum path, because all the eigenvalues of $\mathbf{B}$ are negative, indicating response reduction everywhere *from* the stationary point. The behavior on this path is of the third type listed above.

In Table 1, we followed the path of maximum response. There are six stationary paths in this particular example ($2k$ in general) and we next provide calculations for two more of them. We consider λ values *below* the largest eigenvalue -1.77 . At this eigenvalue, $R = \infty$, so we have to back λ off downward from -1.77 and monitor a smooth path for decreasing R . At some value of λ that is hard to calculate explicitly, R reaches a minimum value, and the ridge path we are following has reached its starting point in the predictor variable space. As λ is decreased further, a new ridge path begins from the shared starting point and R increases again, approaching ∞ as λ declines

^(a)Read up from the gap for the second trace. Read down from the gap for the third trace, whose λ values are indicated by asterisks

and approaches the next-lowest eigenvalue (-4.37). Care is needed in monitoring λ to ensure that the two paths are not confused by an inadvertent leap across the minimum R value (see [3, Chapter 12] for further details and a diagram of the behavior of R). Table 2 shows some selected calculations that take R from its 1.2194 lowest value to just above 2. We see that the “bottoming out point” for R occurs at about $\lambda = -3.04$, after which R begins to ascend again. So $\lambda = -3.04$, approximately, provides the

point $\mathbf{x} = (-0.791, 0.157, 0.914)'$ from which adjacent R versus λ curves rise. These two ridge paths begin at this $\mathbf{x}$ location, and *not at the origin*. Both paths have declining responses.

Extensions of Basic Ridge Analysis

Basic ridge analysis, as described above, has some important practical extensions. It is possible to track

a ridge path on *any* single or on *any* set of designated linear restrictions (i.e., restrictive planes in the experimental space) that may be encountered by the initial best path. One such type of linear restriction occurs, for example, when the experiment is conducted in mixture ingredients adding to 1 (or to any other level specified between 0 and 1) (see [3, Chapter 19] for these extensions).

Historical Notes

Ridge analysis was first introduced in the context of general response surface methodology by Hoerl [4–6]. It was further investigated by Draper [2], who proved several results that Hoerl had suggested without proof. A wide-ranging discussion is given by Hoerl [7]. Applications in **mixture experiments** were discussed by Hoerl [8] and by Draper and Pukelsheim [9–11]. For a complete account, see [3].

Risk Processes

Introduction

The term *risk* is being used in many fields and in different connotations. Risk has been used for many years in decision theory as the expected loss associated with a specific action, under a particular state of nature. Google search yields thousands of entries for “risk processes”. In this article, we focus attention on a class of stochastic processes that may lead to certain undesirable, if not catastrophic events, for example, the claims process in a certain insurance portfolio. The claims arrive from different insured persons at random times. The amount of damage is different from one claim to another. The insurance company starts with certain capital, which steadily grows with the incoming premiums. On the other hand, whenever a payment is done for a claim, its monetary reserve is decreased. The risk to the insurance company is that the monetary reserve will drop below zero. This event is called a *ruin*. It is important to be able to compute the “ruin probability”, and the joint distribution of the “ruin” time and the amount of deficit. The reader is referred to the book of Asmussen entitled *Ruin Probability* [1], for a comprehensive presentation of the theory of ruin probabilities under different stochastic models, and a long list of related references. Another important book on this subject of risk processes is that of Rolski *et al.* entitled *Stochastic Processes for Insurance and Finance* [2]. In this article, we present, in addition to ruin probability, the joint distribution of the ruin time and the amount of deficit for the case of a claiming process that follows a **compound Poisson process** (CPP). In the literature, there are many papers on ruin probability and the distribution of ruin time which are based on other types of stochastic processes. In particular, see Kluppelberg *et al.* [3] for general **Lévy** processes.

Another type of risk process discussed here is that of a *cumulative damage process*, which leads to failure of systems. The damage occurs at random times, and the amount of damage is random. When the cumulative damage reaches a given threshold, the system collapses. We derive the life distribution of systems that are subjected to such failure processes, and the associated hazard functions. The cumulative **damage processes** considered are of the *compound renewal* type.

In the next section, we present the compound **renewal processes** (CRPs) and associated distributions. Then, we study the distributions of stopping times with linear boundaries and CPPs. Some results about the ruin probability and the distributions of its time and its deficit, when the process of claims is a CPP are presented after this. Finally, we discuss the distribution of failure times due to cumulative damage.

Compound Renewal Processes

Let $0 < \tau_1 < \tau_2 < \dots$ be a random sequence of “arrival” times of certain events. Let $T_n = \tau_n - \tau_{n-1}$, $n \geq 1$, where $\tau_0 \equiv 0$. If the random variables $\{T_n, n \geq 1\}$ are independent and identically distributed (i.i.d.), we say that $\{\tau_n, n \geq 0\}$ is a *renewal process*. Let $N(t)$, $t \geq 0$, denote the number of arrivals in the interval $(0, t]$, that is,

$$N(t) = \max(n \geq 0 : \tau_n \leq t) \quad (1)$$

The stochastic process $\{N(t), t \geq 0\}$ is a counting process associated with the renewal process.

Let $F(t)$ be the **cdf** of T_1 . One can immediately show (see [4, pp. 99]) that

$$P\{N(t) = n\} = F^{(n)}(t) - F^{(n+1)}(t), \quad n \geq 0 \quad (2)$$

where $F^{(n)}(t)$ denotes the n -fold convolution of F , that is, $F^{(0)}(t) = 1$ for all $t \geq 0$, $F^{(1)}(t) = F(t)$, and for $n \geq 2$,

$$F^{(n)}(t) = \int_0^t F^{(n-1)}(t-x) dF(x) \quad (3)$$

Let $\{X_n, n \geq 1\}$ be a sequence of i.i.d. random variables, independent of $\{\tau_n, n \geq 0\}$. The process

$$Y(t) = \sum_{n=0}^{N(t)} X_n, \quad t \geq 0 \quad (4)$$

where $X_0 \equiv 0$, is called a *compound renewal process*. In this article we are interested in CRPs with positive jumps. Let $G(x)$ denote the cdf of X_1 . We assume that $G(0) = 0$ and that G is absolutely continuous, with a density g . The cdf of $Y(t)$, at time t , is $H(x; t) = P\{Y(t) \leq x\}$. Notice that $H(0; t) = \bar{F}(t) = 1 - F(t)$ and for $0 < x < \infty$, $H(x; t) = \bar{F}(t) + \int_0^x h(y; t) dy$,

2 Risk Processes

where $h(y; t)$ is the density of $H(\cdot; t)$ on $(0, \infty)$, given by

$$h(y; t) = \sum_{n=1}^{\infty} P\{N(t) = n\} g^{(n)}(y) \quad (5)$$

and $g^{(n)}(y)$ is the n -fold convolution of g . An important subclass of CRP is the CPP, where $\{N(t), t \geq 0\}$ is an ordinary *Poisson process*. In this case,

$$P\{N(t) = n\} = e^{-\lambda t} \frac{(\lambda t)^n}{n!}, \quad n = 0, 1, \dots \quad (6)$$

is the probability function of the Poisson distribution, with mean λt . The parameter $\lambda = E\{N(1)\}$ is called the *intensity of the arrival process*. In this case, the interarrival times $\{T_n, n \geq 1\}$ are exponentially distributed with $E\{T_1\} = 1/\lambda$. We denote by $p(n; \mu)$ and $P(n; \mu)$ the **pdf** and cdf of the Poisson distribution with mean μ . Thus, in the CPP case, the density of $Y(t)$, on $(0, \infty)$ is

$$h(y; t) = \sum_{n=1}^{\infty} p(n; \lambda t) g^{(n)}(y) \quad (7)$$

The corresponding cdf is

$$H(x; t) = \sum_{n=0}^{\infty} p(n; \lambda t) G^{(n)}(x) \quad (8)$$

where $G^{(n)}$ is the n -fold convolution of G . **Moments** of $Y(t)$ can be obtained from the Laplace–Stieltjes transform (LST)

$$\begin{aligned} E\{e^{-\theta Y(t)}\} &= e^{-\lambda t} + \int_0^{\infty} e^{-\theta x} h(x; t) dx \\ &= \exp\{-\lambda t(1 - \phi(\theta))\} \end{aligned} \quad (9)$$

where $\phi(\theta)$ is the Laplace transform (LT) of $g(x)$. Equation (9) is applied to define the Wald martingale associated with a CPP.

Distributions of Stopping Times for CPP

Let $B_L(t, \beta_1)$ and $B_U(t, \beta_2)$, for $0 < \beta_1, \beta_2 < \infty$ be the linear boundaries

$$B_L(t; \beta_1) = -\beta_1 + t \quad (10)$$

and

$$B_U(t; \beta_2) = \beta_2 + t \quad (11)$$

For a CPP $Y(t)$, we define the stopping times

$$T_L(\beta_1) = \inf\{t > 0 : Y(t) = -\beta_1 + t\} \quad (12)$$

and

$$T_U(\beta_2) = \inf\{t > 0 : Y(t) \geq \beta_2 + t\} \quad (13)$$

Notice that $P\{T_L(\beta_1) \geq \beta_1\} = 1$ and $P\{T_L(\beta_1) = \beta_1\} = e^{-\lambda\beta_1}$. As proved by Borovkov [5, p. 66], the density of $T_L(\beta_1)$ on (β_1, ∞) is

$$\psi_L(t; \beta_1) = \frac{\beta_1}{t} h(t - \beta_1; t), \quad t > \beta_1 \quad (14)$$

Let $\rho = \lambda E\{X_1\}$. If $\rho < 1$, then $P\{T_L(\beta_1) < \infty\} = 1$. Since $Y(T_L(\beta_1)) = -\beta_1 + T_L(\beta_1)$, we obtain from the Wald martingale the identity

$$\begin{aligned} E\{\exp\{-\theta Y(T_L(\beta_1)) + \lambda(1 - \phi(\theta))T_L(\beta_1)\}\} \\ = E\{e^{\theta\beta_1} \exp\{-T_L(\beta_1)(\theta - \lambda(1 - \phi(\theta)))\}\} = 1 \end{aligned} \quad (15)$$

for all θ in the domain of convergence of $\phi(\theta)$. Define $\omega(\theta) = \theta - \lambda(1 - \phi(\theta))$. Then, from equation (15), we get

$$E\{e^{-\omega T_L(\beta_1)}\} = e^{-\beta_1 \theta(\omega)} \quad (16)$$

where $\theta(\omega)$ is the inverse function of $\omega(\theta)$. Moments of $T_L(\beta_1)$ can be obtained from equation (16). Indeed,

$$\begin{aligned} E\{T_L(\beta_1)\} &= -\left\{ \frac{d}{d\omega} e^{-\beta_1 \theta(\omega)} \Big|_{\omega=0} \right\} \\ &= \frac{\beta_1}{1 + \lambda\phi'(0)} = \frac{\beta_1}{1 - \rho} \end{aligned} \quad (17)$$

Similarly,

$$E\{T_L^2(\beta_1)\} = \frac{\beta_1^2}{(1 - \rho)^2} + \frac{\beta_1 \lambda E\{X_1^2\}}{(1 - \rho^3)} \quad (18)$$

Moreover, since

$$\begin{aligned} E\{T_L(\beta_1)\} &= \beta_1 e^{-\lambda\beta_1} + \int_0^{\infty} t \psi_L(t; \beta_1) dt \\ &= \beta_1 e^{-\lambda\beta_1} + \beta_1 \int_{\beta_1}^{\infty} h(t - \beta_1; t) dt \\ &= \beta_1 (e^{-\lambda\beta_1} + \int_0^{\infty} h(t; t + \beta_1) dt) \end{aligned} \quad (19)$$

we obtain from equations (17) and (19) the identity

$$\int_0^\infty h(t; t + \beta_1) dt = \frac{1}{1 - \rho} - e^{-\lambda\beta_1} \quad (20)$$

which holds for all distributions G such that $\rho = \lambda E(X_1) = \lambda \int_0^\infty x dG(x) < 1$. In particular for $\beta_1 = 0$, we obtain when $\rho < 1$ the identity

$$\int_0^\infty h(t; t) dt = \frac{1}{1 - \rho} - 1 = \frac{\rho}{1 - \rho} \quad (21)$$

Stadje and Zacks [6] derived the following formula for the (defective) density of $T_U(\beta_2)$, namely

$$\begin{aligned} \psi_U(t; \beta_2) = & \lambda e^{-\lambda t} \bar{G}(t + \beta_2) + \lambda \int_0^{\beta_2+t} h(y; t) \bar{G}(\beta_2 \\ & + t - y) dy \\ & - \lambda \int_0^t h(y + \beta_2; y) \cdot e^{-\lambda(t-y)} \bar{G}(t - y) dy \\ & - \lambda \int_0^t \frac{1}{u} h(t - u + \beta_2; t - u) \\ & \times \left(\int_0^u z \bar{G}(z) h(u - z; u) dz \right) du \end{aligned} \quad (22)$$

This density assumes in some special cases more explicit formulae. For example, if $G(x) = 1 - e^{-\mu x}$, $x \geq 0$, then

$$h(y; t) = \mu \sum_{n=1}^\infty p(n; \lambda t) p(n - 1; \mu y) \quad (23)$$

Moreover, in this exponential case, if $\beta_2 = 0$,

$$\begin{aligned} \psi_U(t; 0) &= \lambda \sum_{n=0}^\infty \frac{1}{n+1} p(n; \lambda t) p(n; \mu t) \\ &= \lambda e^{-(\lambda+\mu)t} \sum_{n=0}^\infty \frac{(\lambda\mu t^2)^n}{(n+1)!n!} \end{aligned} \quad (24)$$

As expected,

$$\begin{aligned} \int_0^\infty \psi_U(t; 0) dt &= \frac{\lambda}{\lambda + \mu} \sum_{n=0}^\infty \frac{(2n)!}{(n+1)!n!} \frac{(\lambda\mu)^n}{(\lambda + \mu)^{2n}} \\ &= \rho \end{aligned} \quad (25)$$

To verify equation (25), use MAPLE, and recall that $\rho = \lambda/\mu$.

Ruin Probability and Associated Distribution under CPP

Consider an insurance company that starts with an initial capital $[\$]\beta$ for a given portfolio. Suppose that the premium paid by the customers is $[\$]p$ per time unit. Thus, after t units of time, the capital reserve, if there were no claims, is $\beta + pt$. Suppose now that claims for damage arrive according to a CPP $Y(t) = \sum_{n=0}^{N(t)} X_n$. The capital reserve at time t is then

$$R(t) = \beta + tp - Y(t), \quad t \geq 0 \quad (26)$$

Ruin occurs at the first time in which $R(t) \leq 0$. This is the stopping time

$$T(\beta, p) = \inf\{t > 0 : Y(t) \geq \beta + tp\} \quad (27)$$

Making the time transformation $t' = tp$, and changing λ to $\lambda' = \lambda/p$, the stopping time $T(\beta, p)$ is reduced to the stopping time $T'_U(\beta) = \inf\{t' > 0 : Y'(t') \geq \beta + t'\}$, where $Y'(t')$ is a CPP with intensity parameter $\lambda' = \lambda/p$. Accordingly, we assume, without loss of generality, that $p = 1$, and apply the results obtained in the section titled “Distributions of Stopping Times for CPP”. The *ruin probability* is defined as

$$\begin{aligned} q(\beta) &= P\{T_U(\beta) < \infty\} \\ &= \int_0^\infty \psi_U(t; \beta) dt \end{aligned} \quad (28)$$

If $\rho \geq 1$ then $q(\beta) = 1$. We are interested in formulae for $q(\beta)$, when $\rho < 1$. Notice that if $p \neq 1$, the condition is $\rho < p$. Let $q^*(s) = \int_0^\infty e^{-s\beta} q(\beta) d\beta$ denote the LT of $q(\beta)$. The formula of $q^*(s)$ is (see [1, p. 65], [4, p. 24])

$$q^*(s) = \frac{1}{s} \cdot \frac{\rho s - \lambda(1 - \phi(s))}{s - \lambda(1 - \phi(s))} \quad (29)$$

where $\phi(s)$ is the LT of the density g . By inversion of $q^*(s)$ one can obtain $q(\beta)$. Accordingly, if $g(x) = \mu e^{-\mu x}$, then $\phi(s) = \mu/(\mu + s)$. Substituting this in equation (29) and inverting yields for the exponential case

$$q(\beta) = \rho \exp\{-\mu(1 - \rho)\beta\} \quad (30)$$

Notice that $q(0) = \rho$, as obtained in equation (25). If G is the Erlang $(2, \mu)$ distribution, $g(x) =$

$\mu^2 x e^{-\mu x}$, $\phi(s) = \mu^2/(\mu + s)^2$, and

$$q(\beta) = \rho e^{-\mu(1-\rho/4)\beta} \left[\cosh\left(\frac{\beta}{2}(\lambda(\lambda + 4\mu))^{1/2}\right) + \frac{(\lambda + \mu) \sinh\left(\frac{\beta}{2}(\lambda(\lambda + 4\mu))^{1/2}\right)}{(\lambda(\lambda + 4\mu))^{1/2}} \right] \quad (31)$$

The exact formula of $q(\beta)$ when G is Erlang $(3, \mu)$ is very complicated. It involves the roots of a cubic polynomial. We therefore develop an alternative formula for $q(\beta)$.

Theorem For $0 < \rho < 1$,

$$q(\beta) = (1 - \rho) \int_0^\infty h(u + \beta; u) du \quad (32)$$

Proof See Perry *et al.* [7].

We derive an explicit formula of equation (32) for the case where G is an Erlang $(2, \mu)$. Notice that $g^{(n)}(x) = [\mu^{2n}/(2n-1)!]x^{2n-1}e^{-\mu x}$, $n \geq 1$. Accordingly

$$h(u + \beta; u) = \mu \sum_{n=1}^\infty p(n; \lambda u) p(2n-1; \mu(u + \beta)) \quad (33)$$

Hence,

$$\begin{aligned} \int_0^\infty h(u + \beta; u) du &= e^{-\mu\beta} \sum_{n=1}^\infty \frac{\lambda^n \mu^{2n}}{n!(2n-1)!} \int_0^\infty y^n (y + \beta)^{2n-1} \\ &\quad \times e^{-(\lambda+\mu)y} dy \end{aligned} \quad (34)$$

From equations (32) and (34), we obtain the formula

$$\begin{aligned} q(\beta) &= (1 - \rho) e^{-\mu\beta} \sum_{n=1}^\infty \left(\frac{\lambda \mu^2}{(\lambda + \mu)^3} \right)^n \binom{3n-1}{n} \\ &\quad \times \left[1 + \frac{1}{(3n-1)!} \sum_{j=0}^{2n-2} \binom{2n-1}{j} \right. \\ &\quad \left. \times (n+j)! (\beta(\lambda + \mu))^{2n-1-j} \right] \end{aligned} \quad (35)$$

Formulae (31) and (35) yield the same results. For example, for $\beta = 5$ and $\rho = 0.6$ we have $q(5) = 0.0383$. If $\rho = 0.8$ we have $q(5) = 0.20958$. Formulae similar to equation (35) can be derived for the cases of G equal to Erlang $(3, \mu)$, Erlang $(4, \mu)$, and so on, while formulae like equation (31) are unavailable.

We remark that the convergence in equation (35) is slow, and one needs to calculate hundreds of terms. The density of the ruin time, $T_U(\beta)$, when $p = 1$, is given by equation (22). We can write this density as

$$\begin{aligned} \psi_U(t; \beta) &= \lambda e^{-\lambda t} \bar{G}(t + \beta) \\ &\quad + \lambda \int_0^{t+\beta} p_U(x; t, \beta) \bar{G}(t + \beta - x) dx \end{aligned} \quad (36)$$

where $p_U(x; t, \beta)$ is the defective density

$$p_U(x; t, \beta) = \frac{d}{dx} P\{Y(t) \leq x, T_U(\beta) > t\} \quad (37)$$

Stadje and Zacks [6] proved that

$$p_U(x; t, 0) = \frac{t-x}{t} h(x; t), \quad t > x \quad (38)$$

and

$$\begin{aligned} p_U(x; t, \beta) &= h(x; t) - e^{-\lambda(t-x+\beta)} \cdot h(x; x - \beta) \\ &\quad - (t - x + \beta) \int_{t-x+\beta}^t \frac{1}{u} h(u - t \\ &\quad + x - \beta; u) h(t - u + \beta; t - u) du \end{aligned} \quad (39)$$

Substituting equation (39) in equation (36), we obtain equation (22). The *deficit* at ruin time, when $p = 1$, is

$$D_U(\beta) = Y(T_U(\beta)) - \beta - T_U(\beta) \quad (40)$$

This random variable is generally dependent on $T_U(\beta)$. The joint density of $(T_U(\beta), D_U(\beta))$ is

$$\begin{aligned} \tilde{\psi}_U(t, d; \beta) &= \lambda e^{-\lambda t} g(t + \beta + d) \\ &\quad + \lambda \int_0^{t+\beta} p_U(x; t, \beta) g(t + \beta \\ &\quad + d - x) dx \end{aligned} \quad (41)$$

One can immediately verify that, in the exponential case, when $g(x) = \mu e^{-\mu x}$,

$$\tilde{\psi}_U(t, d; \beta) = \psi_U(t; \beta) \cdot \mu e^{-\mu d}, \quad \text{all } 0 < t, d < \infty \quad (42)$$

that is, $T_U(\beta)$ and $D_U(\beta)$ are independent. This is the only case where $T_U(\beta)$ and $D_U(\beta)$ are independent. On this topic, see also Gerber and Shiu [8].

We conclude this section with a few comments. It is often the case that the parameter ρ may increase at some unknown *change point*. In such a case, the ruin probability might increase dramatically. Insurance companies should detect such a change point as soon as possible in order to avoid ruin by changing the premium p . Other methods common these days are based on a bonus–malus system. In such a system the individual premium increases or decreases according to the history of claims. For a Markovian bonus–malus system, see Zacks and Levikson [9].

Failure Times due to Cumulative Damage

Consider a damage process, which, at random times, brings a random amount of damage to a system. We model such a process by a CRP, $Y(t) = \sum_{n=0}^{N(t)} X_n$, where $X_0 \equiv 0$, and $\{X_n, n \geq 1\}$ are i.i.d. positive random variables, representing the damage to the system. The cdf of $Y(t)$ is

$$H(y; t) = \sum_{n=0}^{\infty} (F^{(n)}(t) - F^{(n+1)}(t)) G^{(n)}(y) \quad (43)$$

where F is the cdf of the interarrival time and G is the cdf of X_1 . Let β , $0 < \beta < \infty$, be a known specified threshold of the system. The system fails as soon as $Y(t)$ exceeds β . Thus, let

$$T(\beta) = \inf\{t > 0 : Y(t) \geq \beta\} \quad (44)$$

Since $\{Y(t), t \geq 0\}$ is an upward jump process, it is a nondecreasing function of t . Accordingly

$$P\{T(\beta) > t\} = H(\beta - 0; t) \quad (45)$$

Obviously, $P\{T(\beta) < \infty\} = 1$, and thus $\lim_{t \rightarrow \infty} H(\beta - 0; t) = 0$. The density function of $T(\beta)$ is

$$p_T(t; \beta) = f(t) \bar{G}(\beta) + \sum_{n=2}^{\infty} f^{(n)}(t) (G^{(n-1)}(\beta) - G^{(n)}(\beta)) \quad (46)$$

Let $S_n = \sum_{i=0}^n X_i$, and define

$$N^*(t) = \max\{n \geq 0 : S_n \leq t\}, \quad t \geq 0 \quad (47)$$

$\{N^*(t), t \geq 0\}$ is a renewal process associated with $\{X_i, i \geq 0\}$. Thus, $P\{N^*(\beta) = n - 1\} = G^{(n-1)}(\beta) - G^{(n)}(\beta)$, $n \geq 1$. We thus obtain

$$p_T(t; \beta) = \sum_{n=1}^{\infty} f^{(n)}(t) P\{N^*(\beta) = n - 1\} \quad (48)$$

The following theorem was proved by Zacks [10].

Theorem *If the interarrival time T_1 has a moment of order m , μ_m ($m \geq 1$), then*

$$E\{T^m(\beta)\} = \sum_{n=1}^{\infty} M_{n,m} P\{N^*(\beta) = n - 1\} \quad (49)$$

where

$$M_{n,m} = E \left\{ \left(\sum_{i=1}^n T_i \right)^m \right\} \quad (50)$$

Hence,

$$V\{T(\beta)\} = \sigma^2(1 + E\{N^*(\beta)\}) + \mu_1^2 V\{N^*(\beta)\} \quad (51)$$

where μ_1 is the expected value of T_1 and $\sigma^2 = V\{T_1\}$.

We consider now the special case of CPP with exponential damage, that is, $G(x) = 1 - e^{-\mu x}$, $x \geq 0$. Let $\zeta = \mu\beta$. The reliability function is $R(t; \lambda, \zeta) = P\{T(\beta) > t\}$. One can verify that

$$R(t; \lambda, \zeta) = \sum_{n=0}^{\infty} p(n; \zeta) P(n; \lambda t) \quad (52)$$

where $P(n; \lambda t) = \sum_{j=0}^n p(j; \lambda t)$. Accordingly, the density of the failure time $T(\beta)$ is

$$f_T(t; \lambda, \zeta) = \lambda \sum_{n=0}^{\infty} p(n; \zeta) p(n; \lambda t) \quad (53)$$

Furthermore, in this case

$$E\{T(\beta)\} = \frac{1 + \zeta}{\lambda} \quad (54)$$

and

$$V\{T(\beta)\} = \frac{1 + 2\zeta}{\lambda^2} \quad (55)$$

The hazard rate function in this case is

$$h_z(t; \lambda, \zeta) = \lambda \frac{\sum_{n=0}^{\infty} p(n; \zeta) p(n; \lambda t)}{\sum_{n=0}^{\infty} p(n; \zeta) P(n; \lambda t)} \quad (56)$$

One can show that $t \mapsto h_z(t; \lambda, \zeta)$ is strictly increasing, with $h_z(0; \lambda, \zeta) = \lambda e^{-\zeta}$ and $\lim_{t \rightarrow \infty} h_z(t; \lambda, \zeta) = \lambda$.

Zacks [11] studied another class of failure time distributions caused by nonhomogeneous compound Poisson damage processes. For a nonhomogeneous Poisson process with **intensity function** $\lambda(t)$, if $m(t) = \int_0^t \lambda(s) ds$, the cumulative damage at time t has a cdf

$$H(y; t) = \sum_{n=0}^{\infty} p(n; m(t)) G^{(n)}(y) \quad (57)$$

The special case with $m(t) = (\lambda t)^\nu$, $0 < \nu < \infty$, is called a *compound Weibull process (CWP)*. A CWP with exponential damage distribution G , yields the reliability function

$$R(t; \lambda, \nu, \zeta) = \sum_{n=0}^{\infty} p(n; \zeta) P(n; (\lambda t)^\nu) \quad (58)$$

Equation (52) is a special case for $\nu = 1$. As before, $\zeta = \mu\beta$. The failure time associated with equation (58) has the density function

$$f(t; \lambda, \nu, \zeta) = \lambda \nu (\lambda t)^{\nu-1} \sum_{j=0}^{\infty} p(j; \zeta) p(j; \lambda t)^\nu \quad (59)$$

Notice that

$$\lim_{\zeta \rightarrow 0} f(t; \lambda, \nu, \zeta) = \lambda \nu (\lambda t)^{\nu-1} \cdot e^{-(\lambda t)^\nu} \quad (60)$$

which is the common Weibull distribution. It shows that the Weibull life distribution is the case where the first shock leads to failure (zero threshold).

In the literature there are other stochastic models of damage and wearout. Abdel-Hameed [12] used *gamma processes*. This was done also by Durfresne *et al.* [13]. Faddy [14] used *phase-type* distributions. See also the article of Singpurwalla [15].

Brownian Motion

Introduction

Brownian motion is the continuous stochastic process *par excellence*. All continuous martingales are time-changed Brownian motions. All continuous **Markov processes** are constructed from Brownian motions. Many classical problems in partial differential equations are solved by probabilistic methods using Brownian motion. Many stochastic processes can be approximated well by Brownian motions or processes related to them. Brownian motion is central to the theory and application of stochastic processes and statistical analysis.

It is named after the botanist Robert Brown, who observed in 1826 that microscopic particles suspended in a fluid move with jumps and starts as if alive. Physicists use the term *Brownian motion* for this physical phenomenon itself, for which there have been many mathematical models built by Einstein, Perrin, Langevin, Smoluchovsky, Uhlenbeck, Wang, and Ornstein, to name a few. In the mathematical literature, the term is used for the model first introduced by Einstein in 1905, which is also the mathematical model introduced by Bachelier [1] for the evolution of stock prices. Nelson [2] has an enlightening account of this history. We shall use the term as it is customary in mathematics.

A real-valued stochastic process is called a *Brownian motion* if it is continuous, temporally homogeneous, and has independent increments. Continuity of paths is a regularity condition. Temporal homogeneity signals that the underlying mechanism producing the randomness remains unchanged over time. *Independence of increments* refers to the mutual independence of the displacements over disjoint time intervals.

Every such process is necessarily Gaussian. We use the term *Wiener process* for the standard case where the initial state is zero, the mean vanishes, and the variance increases with time at unit rate; we denote it by W . Then, every Brownian motion X has the form

$$X_t = X_0 + \mu t + \sigma W_t, \quad t \geq 0 \quad (1)$$

where μ and σ are deterministic constants and X_0 is independent of the Wiener process W . Here, μ is

called the *drift rate* and σ the *volatility* (and σ^2 is called the *diffusion coefficient* in earlier literature).

Symmetry, Scaling, and Time Reversal

The Wiener process has certain invariance properties that enhance its value. It is symmetric: W and its negative have the same law. It has scale invariance: setting

$$\widehat{W}_t = \frac{1}{\sqrt{c}} W_{ct}, \quad t \geq 0 \quad (2)$$

yields another Wiener process $\widehat{W}$. It has time reversibility:

$$\widetilde{W}_t = t W_{1/t}, \quad t \geq 0 \quad (3)$$

is again a Wiener process.

Scale invariance shows that a Wiener process is strictly stable with index 2; *self-similar* is another term. This property puts it at the center of symmetric stable Lévy processes: every such process is obtained from a Wiener process by subordination to an increasing stable process.

Martingale Connection

Wiener process is the basic continuous martingale. It is itself a martingale, and putting

$$Y_t = W_t^2 - t, \quad t \geq 0 \quad (4)$$

yields another martingale Y . Indeed, if the process W is a continuous martingale and Y is also a martingale, then W is necessarily a Wiener process; this is Lévy's characterization of the Wiener process as a martingale. Another, very useful characterization is *via* the exponential martingale:

$$X_t = \exp\left(r W_t - \frac{1}{2} r^2 t\right), \quad t \geq 0 \quad (5)$$

is a martingale for each real-number r if and only if W is a Wiener process.

Sample Paths and Stochastic Calculus

Some of the fascination with Brownian motion comes from the intricacies of its sample paths.

2 Brownian Motion

Although continuous, almost every path is nowhere differentiable and has infinite total variation over every open interval, but has finite quadratic variation over every interval (the value being equal to the length of the interval); see Freedman [3] for the precise details. Thus, the paths are highly irregular and highly oscillatory, but the oscillations are “small” in magnitude. Hence, the differential dW does not have a meaning in the ordinary sense, but Itô was able to give it a meaning in the sense of convergence in probability. The resulting stochastic calculus is an extension of the ordinary calculus and has proved to be of immense value in applications ranging from engineering to finance. We refer to Karatzas and Shreve [4] and Revuz and Yor [5] on these matters.

Hitting Times

For fixed $\alpha > 0$, let T_α denote the first time that the Wiener process W hits the point α . A probabilistic argument based on the strong Markov property shows that T_α has the same distribution as α^2/Z^2 , where Z is a standard Gaussian variable (normal with mean 0 and variance 1).

It follows that T_α is almost surely finite; the Wiener process will hit α with probability one, however large α maybe. The expected time it takes to hit α is equal to infinity (since α^2/Z^2 has infinite expectation), however small $\alpha > 0$ maybe. It is easy, using the well-known density for Z , to obtain the **probability density function** for T_α : it is

$$\frac{\alpha e^{-\alpha^2/2t}}{\sqrt{2\pi t^3}}, \quad t > 0 \quad (6)$$

Engineers and statisticians call this the *inverse Gaussian distribution*, probabilists have no name for it. It is an infinitely divisible distribution; it is strictly stable with index $1/2$. In fact, as a stochastic process indexed by α , the process (T_α) is an increasing pure-jump Lévy process which is, further, strictly stable with index $1/2$.

Maximum

Let M_t be the maximum achieved by the Wiener process W during the time interval from 0 to t . This defines an increasing continuous process M . Note that, for each time t and point $\alpha \geq 0$, the event that

$T_\alpha < t$ is the same as the event $M_t > \alpha$. Since T_α has the same distribution as α^2/Z^2 , this implies that

$$\begin{aligned} \mathbb{P}\{M_t > \alpha\} &= \mathbb{P}\left\{\frac{\alpha^2}{Z^2} < t\right\} \\ &= \mathbb{P}\left\{\sqrt{t} |Z| > \alpha\right\} = \mathbb{P}\{|W_t| > \alpha\} \end{aligned} \quad (7)$$

In other words, for each t fixed, M_t has the same distribution as $|W_t|$. In particular, then,

$$\mathbb{E}M_t = \sqrt{\frac{2t}{\pi}}, \quad \mathbb{E}M_t^2 = t \quad (8)$$

Since W touches every α with probability one, the maximum process M increases without bound. By symmetry, the minimum process must be decreasing without bound. This implies, in particular, that W crosses and recrosses the point 0 without end, that is, the zeros of W form an unbounded random subset of the positive real line.

Zeros of W

Consider the random set R of times t for which $W_t = 0$. The set R has many of the features of the Cantor set. Almost surely, R is closed, unbounded, and everywhere dense in itself, and also has Lebesgue measure zero, empty interior, and the power of the continuum.

The random set R is regenerative: for every stopping time T belonging to R , its future after T is an independent replica of R . It follows from a theorem of Maisonneuve [6] that there exists an increasing Lévy process $S = (S_\alpha)$ such that the set R is the range of S , that is,

$$R = \{t \geq 0 : S_\alpha = t \text{ for some } \alpha \geq 0\} \quad (9)$$

The process S turns out to have the same probability law as the hitting process (T_α) ; in other words, S is a strictly increasing pure-jump **Lévy process** and is stable with index $1/2$.

Local Times

For each time t , let L_t be the infimum of the set of numbers α for which S_α exceeds t . In short, L is the functional inverse of S . A closer examination of

this definition shows that L is a continuous increasing process that increases when and only when W is at the point 0. Thus, L may be considered to be a random clock whose mechanism is so rigged that the clock advances when and only when W is at 0. For this reason, L is called the *local time process at 0*.

The process L has the same probability law as the maximum process M . This is because L bears the same relation to (S_α) as M does to (T_α) , and the processes (S_α) and (T_α) have the same law. Indeed, the two-dimensional processes $(M, M - W)$ and $(L, |W|)$ have the same probability law. This implies that $L - |W|$ has the same probability law as $M - (M - W) = W$, that is, $L - |W|$ is again a Wiener process.

Markovian Connection

Brownian motion is a special Markov process. We consider the case of the d -dimensional Brownian motion $X = X_0 + W$, where

$$W = (W^{(1)}, \dots, W^{(d)}) \quad (10)$$

is the d -dimensional Wiener process, that is, the components $W^{(i)}$ are independent one-dimensional Wiener processes. Then, the increment over an interval of length t has the d -dimensional Gaussian distribution with mean 0 and variance–**covariance** matrix equal to t times the identity matrix. Thus, X is a Markov process with transition probability density

$$p(t, x, y) = \frac{1}{\sqrt{(2\pi t)^d}} \exp\left(-\frac{1}{2t}|y - x|^2\right) \quad (11)$$

here $|x|$ denotes the length of the d -dimensional vector x .

Transition Semigroup

Define the operators P_t by

$$P_t f(x) = \int dy \, p(t, x, y) f(y) \quad (12)$$

for bounded Borel functions f on the d -dimensional Euclidean space. They have the semigroup property:

$$P_t P_s = P_{s+t} \quad (13)$$

which is a consequence of the Chapman–Kolmogorov equation

$$\int dy \, p(s, x, y) p(t, y, z) = p(s+t, x, z) \quad (14)$$

Infinitesimal Generator

Let A denote the infinitesimal generator of the semigroup (P_t) . Let f have second-order partial derivatives that are continuous and bounded. Note that

$$P_t f(x) - f(x) = \int dy \, \frac{e^{-|y|^2/2}}{\sqrt{(2\pi)^d}} \times [f(x + \sqrt{t} y) - f(x)] \quad (15)$$

and expand f in a Taylor series in $\sqrt{t}$. This shows that

$$A f(x) = \lim_{t \rightarrow 0} \frac{1}{t} [P_t f(x) - f(x)] = \frac{1}{2} \Delta f(x) \quad (16)$$

where Δ is the Laplace operator:

$$\Delta = \sum_{i=1}^d \frac{\partial^2}{\partial x_i^2} \quad (17)$$

Then, the differential equation

$$\frac{d}{dt} P_t = A P_t \quad (18)$$

implies that $u(t, x) = P_t f(x)$ satisfies the heat equation

$$\frac{\partial}{\partial t} u = \frac{1}{2} \Delta u \quad (19)$$

Connections to Classical Analysis

The appearance of the Laplace operator and the heat equation signal that there are deep connections between Brownian motion and classical analysis. Many partial differential equations can be related to Brownian motion or its generalizations, the diffusions. Often, then, probabilistic methods can be used to obtain solutions, and/or simulation studies coupled with statistical analysis will yield good approximations.

In particular, as Doob and Kakutani have observed in the 1940s, there is a one-to-one correspondence between the theories of potentials and Brownian motion; see Port and Stone [7] for an account. This opened up the possibility of generalizing potential theory by replacing Brownian motion with more general Markov processes; see Hunt [8, 9] for the seminal work, and Blumenthal and Gettoor [10] for a careful account. Finally, Doob [11] is the masterwork on the general theory that connects potentials, martingales, and Markov processes.

ERHAN ÇINLAR

Poisson Processes

Introduction

Many processes in everyday life that “count” events up to a particular point in time can be accurately described by the so-called Poisson process, named after the French scientist Siméon Poisson (1781–1840; appointed as full professor at the Ecole Polytechnique, Paris, in 1806 as a successor of Fourier). An (ordinary) Poisson process is a special Markov process (see **Markov Processes**), in continuous time, in which the only possible jumps are to the next higher state. A Poisson process may also be viewed as a counting process that has particular, desirable, properties. In this article we shall first give a few equivalent definitions of the Poisson process. Subsequently, we describe the relation between the Poisson process and the (negative) exponential distribution; we then show relations between the Poisson process and the uniform distribution, and between the Poisson process and the binomial distribution. Next we discuss “Poisson conservation” results that are extremely useful in, for example, analyzing queuing networks in which customers arrive according to a Poisson process. The next section is devoted to the uniformization principle, a useful principle in studying the transient behavior of **Markov processes**. Finally, a generalization of the Poisson process, *viz.*, the compound Poisson process is considered.

Definitions of the Poisson Process

A counting process $\{C(t), t \geq 0\}$ is a stochastic process that keeps count of the number of events that have occurred up to time t . Obviously, $C(t)$ is nonnegative and integer valued for all $t \geq 0$. Furthermore, $C(t)$ is nondecreasing in t . $C(t) - C(s)$ equals the number of events in the time interval $(s, t]$, $s < t$.

$C(t)$ could, for example, denote the number of arrivals of customers at a railway station in $(0, t]$, or the number of accidents on a particular highway in that time interval, or the number of births of animals in a particular zoo in $(0, t]$, or the number of calls to a telephone call center during that period. A Poisson process is a counting process that has the desirable additional properties that the numbers of events

in disjoint intervals are independent (*independent increments*) and that the number of events in any given interval depends only on the length of that interval, and not on its particular position in time (*stationary increments*). In the case of the arrivals at the railway station, the stationarity assumption is clearly not fulfilled; there will be many more arrivals between 5 p.m. and 6 p.m. than between, say, 5 a.m. and 6 a.m. Still, one might wish to study the arrival process at the railway station during the rush hour. Restricting oneself to subsequent working days between 5 p.m. and 6 p.m. does allow one to use the stationary increments assumption.

Similarly, the independent increments assumption may be violated in the zoo example, but it will be a reasonably accurate representation of reality in many cases. From the viewpoint of mathematical tractability, these two properties are extremely important. We refer to Feller [1] for an extensive and lucid discussion of stochastic processes with stationary and independent increments. In the sequel we make an additional assumption, which reduces counting processes with stationary and independent increments to Poisson processes.

Definition 1 A Poisson process $\{N(t), t \geq 0\}$ is a counting process with the following additional properties:

1. $N(0) = 0$.
2. The process has stationary and independent increments.
3. $\mathbb{P}(N(h) = 1) = \lambda h + o(h)$ and $\mathbb{P}(N(h) \geq 2) = o(h)$, $h \downarrow 0$, for some $\lambda > 0$.

Above, the $o(h)$ symbol indicates that the ratio $\frac{\mathbb{P}(N(h) \geq 2)}{h}$ tends to zero for $h \downarrow 0$.

An equivalent definition is as follows:

Definition 2 A Poisson process $\{N(t), t \geq 0\}$ is a counting process with the following additional properties:

1. $N(0) = 0$.
2. The process has stationary and independent increments.
3. $\mathbb{P}(N(t) = n) = e^{-\lambda t} \frac{(\lambda t)^n}{n!}$, $n = 0, 1, 2, \dots$

Of course, the last property states that the number of events in any interval of length t is Poisson

2 Poisson Processes

distributed with mean λt . λ is called the *rate* of the Poisson process. It readily follows that the probability generating function of $N(t)$ is given by $\mathbb{E}[z^{N(t)}] = \sum_{n=0}^{\infty} z^n \mathbb{P}(N(t) = n) = e^{-\lambda(1-z)t}$. Differentiation yields $\mathbb{E}[N(t)] = \lambda t$, $\mathbb{E}[N(t)(N(t) - 1)] = (\lambda t)^2$, and hence $\text{Var}(N(t)) = \lambda t$.

The last property of Definition 1 may look awkward at first sight, but is insightful. It states that having two or more events in a small time interval is extremely unlikely, while the probability of a single event is approximately proportional to the length of that small interval.

Remark 1 A Poisson process arises naturally in large populations. Consider such a population of size n , and observe the number of events of a certain type, occurring during a unit time interval. For example, if the probability of an individual calling a call center between, say, 9:00 and 9:01 is p , then the total number of calls during that minute is binomially distributed with parameters n and p . If n becomes large and p gets small such that $np \rightarrow \lambda > 0$, the result is a Poisson process with rate λ of calls per minute.

We close this section by giving yet another, equivalent, definition of the Poisson process.

Definition 3 A Poisson process $\{N(t), t \geq 0\}$ is a counting process with the following additional properties:

1. $N(0) = 0$.
2. The only changes in the process are unit jumps upward. The intervals between jumps are independent, exponentially distributed random variables with mean $1/\lambda$, $\lambda > 0$.

Notice that part (3) of Definition 2 indeed implies that $\mathbb{P}(N(t) = 0) = e^{-\lambda t}$, that is, that the interval until the first event is exponentially distributed with mean $1/\lambda$, denoted $\exp(\lambda)$. The exponential distribution has the memoryless property (uniquely among all continuous distributions): If $T \sim \exp(\lambda)$, then $\mathbb{P}(T > s + t | T > s) = \mathbb{P}(T > t)$. It should also be noted that the memoryless property of the exponential distribution and the independence of successive jump intervals indeed imply that increments are stationary and independent.

Each of the above equivalent definitions has features that make it useful for deriving particular properties, as we shall see in the sequel.

Relation between the Poisson Process and the Exponential Distribution

There is an intimate relation between the Poisson process and the exponential distribution, as already revealed by Definition 3. In this section we go somewhat deeper into this relation.

Let T_1 denote the time of the first event of a Poisson process and let T_n denote the time between the $(n-1)$ th and the n th event, $n = 2, 3, \dots$. Let $S_n = \sum_{i=1}^n T_i$ denote the instant of the n th event. An important observation is that

$$N(t) \geq n \iff S_n \leq t \quad (1)$$

That is, the number of events during $(0, t]$ is at least n if the time until the n th event is no larger than t . Hence

$$\mathbb{P}(N(t) \geq n) = \mathbb{P}(S_n \leq t), \quad n = 1, 2, \dots, t \geq 0 \quad (2)$$

Definition 2 implies that $\mathbb{P}(N(t) \geq n) = \sum_{j=n}^{\infty} e^{-\lambda t} \frac{(\lambda t)^j}{j!}$, and hence

$$\mathbb{P}(S_n \leq t) = 1 - \sum_{j=0}^{n-1} e^{-\lambda t} \frac{(\lambda t)^j}{j!}, \quad n = 1, 2, \dots, (t \geq 0) \quad (3)$$

This is the well-known result that the sum of n independent, $\exp(\lambda)$ distributed, random variables is $\text{Erlang}(n; \lambda)$ distributed. In particular, $T_1 = S_1$ is $\exp(\lambda)$. The density of this Erlang distribution equals $\lambda e^{-\lambda t} \frac{(\lambda t)^{n-1}}{(n-1)!}$, $n = 1, 2, \dots, (t > 0)$, which also follows from the reasoning below:

$$\begin{aligned} \mathbb{P}(t < S_n \leq t + h) &= \mathbb{P}(N(t) = n - 1, \text{ one event in } (t, t + h]) \\ &\quad + o(h) \\ &= \mathbb{P}(N(t) = n - 1) \mathbb{P}(\text{one event in } (t, t + h]) \\ &\quad + o(h) \\ &= e^{-\lambda t} \frac{(\lambda t)^{n-1}}{(n-1)!} \lambda h + o(h) \end{aligned} \quad (4)$$

Now divide by h and let $h \downarrow 0$ to get the density.

A well-known property of the exponential distribution is that it has a constant failure rate equal to λ : if T is $\exp(\lambda)$ distributed, then

$$\mathbb{P}(T \leq t + h | T \geq t) = \lambda h + o(h), \quad h \downarrow 0 \quad (5)$$

implying that $\lim_{h \downarrow 0} \mathbb{P}(T \leq t + h | T \geq t)/h = \lambda$. We have also seen this property in Definition 1 of the Poisson process.

To illustrate the concept of failure rate, consider a probability distribution function $F(\cdot)$ describing the lifetime of a device and denote its density by $f(\cdot)$. Then the failure rate of $F(\cdot)$ is defined as $r(t) = f(t)/[1 - F(t)]$; $r(t) dt$ gives the probability that the device fails during $(t, t + dt]$, given that it is “alive” at time t .

Relations between the Poisson Process and the Uniform Distribution

In this section we discuss a property of the Poisson process that is often very useful in applications. If exactly one event of a Poisson process has occurred in $(0, t]$, then the time of that occurrence is uniformly distributed on $(0, t)$. The informal explanation is that, because of the stationary and independent increments, each subinterval of equal length in $(0, t)$ has the same probability to contain that event. The formal derivation is

$$\begin{aligned} \mathbb{P}(T_1 \leq s | N(t) = 1) &= \frac{\mathbb{P}(\text{one event in } (0, s], \text{ no event in } (s, t])}{\mathbb{P}(N(t) = 1)} \\ &= \frac{\mathbb{P}(N(s) = 1) \mathbb{P}(N(t-s) = 0)}{\mathbb{P}(N(t) = 1)} = \frac{s}{t}, \\ & \quad 0 \leq s \leq t \end{aligned} \quad (6)$$

More generally, the following can be proved for a Poisson process: If $N(t) = n$, then the event times $S_1, \dots, S_n$ are distributed like the order statistics of n independent random variables that are uniformly distributed on $(0, t)$.

The property that a Poisson arrival “is just as likely to occur in any interval” has proved to be extremely useful in, for example, queuing theory. Firstly, it forms the basis of the well-known PASTA (*Poisson Arrivals See Time Averages*) property. In queuing terms this property states that an outside observer, arriving to a queue according to a Poisson process,

sees the system as if it were in steady state. Consider, for example, an $M/G/s$ queue. This is a queuing model in which arrivals occur according to a Poisson process (M), requiring a generally distributed (G) service time at one of s servers. The PASTA property implies for the $M/G/s$ queue that the number of customers seen by an arriving customer has the same distribution as the steady-state number of customers. The PASTA property was first rigorously proved by Wolff [2].

Another well-known application of the property that Poisson arrivals are uniformly distributed over an interval is provided by the $M/G/\infty$ queue [3]. This is an $M/G/s$ queue with an ample ($s = \infty$) number of servers. The $M/G/\infty$ system may be used, for example, to model certain production or transportation systems; the customers might then be pallets moving on a conveyor belt, or cars on a road. Given that n arrivals have occurred in the $M/G/\infty$ system up to t , the above property specifies the distribution of the arrival epochs. One can then easily determine the probability that such a customer, who has arrived in $(0, t]$, is still present at t . Thus one can obtain the distribution of the number of customers $L(t)$ in the $M/G/\infty$ system at t , starting from an empty system at 0 (*cf.* Takács [3, Chapter 3]). It turns out that $L(t)$ has a Poisson distribution with time-dependent rate $\lambda \int_0^t \mathbb{P}(B > y) dy$, B denoting service time of an individual customer. When $t \rightarrow \infty$, one gets the so-called stationary distribution of $L(t)$, which is Poissonian with rate $\lambda \mathbb{E}B$. Furthermore, the number of customers served in $(0, t]$ is also Poisson distributed, with rate $\lambda \int_0^t \mathbb{P}(B \leq y) dy$, and it is statistically independent of the process $\{L(t), t \geq 0\}$.

Relations between the Poisson Process and the Binomial Distribution

Two important consequences of the stationary and independent increments properties are the following:

1. For any $t > u \geq 0$ and integers $n \geq k$,

$$\begin{aligned} \mathbb{P}(N(u) = k | N(t) = n) &= \binom{n}{k} \left(\frac{u}{t}\right)^k \\ &\quad \times \left(1 - \frac{u}{t}\right)^{n-k}, \quad k = 0, 1, \dots, n \end{aligned} \quad (7)$$

That is, given that n events occurred in $(0, t]$, the probability that k of them occurred in

- (0, u] is given by the binomial distribution with parameters n and “success” probability $p = u/t$.
2. For two independent Poisson processes $N_1(t)$ and $N_2(t)$, having rates λ_1 and λ_2 , respectively,

$$\begin{aligned} \mathbb{P}(N_1(t) = k | N_1(t) + N_2(t) = n) &= \binom{n}{k} \\ &\times \left(\frac{\lambda_1}{\lambda_1 + \lambda_2} \right)^k \left(\frac{\lambda_2}{\lambda_1 + \lambda_2} \right)^{n-k}, \\ k &= 0, 1, \dots, n \end{aligned} \quad (8)$$

This result implies, in particular, that if two such processes “compete” on which one will be the first to occur, the probability that $N_i(t)$ is “quicker” is given by $\frac{\lambda_i}{\lambda_1 + \lambda_2}$, $i = 1, 2$.

See again Remark 1 for yet another relation between the Poisson process and the binomial distribution.

Conservation Properties

The Poisson process satisfies some conservation properties that greatly enhance its applicability. In particular, random splitting of a Poisson process results in independent Poisson processes; similarly, merging independent Poisson processes again produces a Poisson process. We now formalize these statements, without proof.

Proposition 1 *Suppose that events occur according to a Poisson process $\{N(t), t \geq 0\}$ of rate λ . Further, suppose that each event is classified as a type i event with probability $p_i \in (0, 1)$, $i = 1, \dots, K$. Let $N_i(t)$ denote the number of type- i events in $(0, t]$. Then $\{N_1(t), t \geq 0\}, \dots, \{N_K(t), t \geq 0\}$, are independent Poisson processes with corresponding rates $\lambda p_1, \dots, \lambda p_K$.*

Indeed, it is easy to see that an arbitrary interval of length h will contain a type- i event with probability $\lambda p_i h + o(h)$, $h \downarrow 0$. The independence of the various Poisson processes is less obvious. But remember that the knowledge that, say, $N_1(t) = j$ just implies that j out of the t/h intervals of length h contain a type-1 event; it does not really imply anything about the occurrence of events of other types.

Now consider the dual situation, in which there are K independent Poisson processes $\{N_1(t),$

$t \geq 0\}, \dots, \{N_K(t), t \geq 0\}$ with corresponding rates $\lambda_1, \dots, \lambda_K$, and in which we count together all events of all these processes.

Proposition 2 *The sum process $\{N(t), t \geq 0\}$ of K independent Poisson processes $\{N_i(t), t \geq 0\}$, $i = 1, \dots, K$, with $N(t) = \sum_{i=1}^K N_i(t)$, $t \geq 0$, is a Poisson process with rate equal to the sum $\sum_{i=1}^K \lambda_i$ of the rates of the individual processes.*

This proposition can be easily proved using any of the three Definitions 1, 2, or 3. For example, it is straightforward (and intuitive) to verify the following property of Definition 1: $\mathbb{P}(N(h) = 1) = \lambda h + o(h)$, from the similar property of the individual Poisson processes. The proposition also follows using the multiplication property of probability generating function (PGF) of independent random variables and using the fact that the PGF of $N_i(t)$ equals $e^{-\lambda_i(1-z)t}$. Alternatively, Definition 3 also works well here; use the fact that the minimum of K independent $\exp(\lambda_i)$ distributed random variables is $\exp\left(\sum_{i=1}^K \lambda_i\right)$ distributed, combined with the memoryless property of the exponential distribution.

Networks of Queues

In 1956 Paul Burke [4] proved the output theorem, a result that plays a crucial role in the study of networks of **queues**. This theorem states the following: Consider an $M/M/s$ queue, viz., a queuing system with s servers, first-come-first-served service operation, a $\text{Poisson}(\lambda)$ arrival process of customers, and independent $\exp(\mu)$ distributed service times. Assume that $\lambda < s\mu$, implying that the process of number of customers in the system reaches an equilibrium distribution. Then the output process of the $M/M/s$ queue, counting the number of departures in $(0, t]$, is a Poisson process with rate λ . It can be shown that, when $s < \infty$, the above “conservation of Poisson flows” property only holds for the multiserver queue when service times are exponential. However, when $s = \infty$, it holds for general service times.

In 1957 Reich [5] provided an extremely elegant proof of the output theorem. He observed that the process constituted by the number of customers in the $M/M/s$ system is a reversible stochastic process. Viewed backward in time, this process is statistically indistinguishable from the original process. The output process of the reversed-in-time $M/M/s$ queue

coincides with the Poisson input process of the original $M/M/s$ queue, and hence is also Poissonian. Using once more the reversibility property leads to the conclusion that the output process of the original $M/M/s$ queue is a Poisson process.

The previously discussed properties of conservation of Poisson flows under merging, splitting, and passing through an $M/M/s$ system allow one to analyze the queue-length process in a network of queues $Q_1, \dots, Q_K$, all having external Poisson arrival processes, exponential service times, possibly multiple servers, and with Markovian routing of customers from queue to queue. Indeed, the output of an $M/M/s_i$ queue Q_i is Poisson. If a fraction p_{ij} is routed to Q_j , then the resulting flow is again Poisson; and if it merges with another, independent, Poisson process, the resulting process is also Poisson. This is only part of the explanation why such networks of exponential multiserver queues have a joint queue-length distribution that exhibits a product form, the i th term of the product corresponding to an $M/M/s_i$ queue Q_i in isolation. For an excellent exposition of the theory of product-form queueing networks we refer to Kelly [6].

Uniformization

In many application areas it is important to determine the *transient* behavior of a Markov process. Consider a Markov process $\{X(t), t \geq 0\}$, with transition probabilities P_{ij} and visit times to all states being exponentially distributed with the *same* mean $1/\lambda$. Hence the number of transitions in $(0, t]$ is Poisson distributed with mean λt . Denoting the corresponding Poisson process by $\{N(t), t \geq 0\}$ we have the following:

$$\mathbb{P}(X(t) = j | X(0) = i) = \sum_{n=0}^{\infty} P_{ij}^{(n)} e^{-\lambda t} \frac{(\lambda t)^n}{n!} \quad (9)$$

where $P_{ij}^{(n)}$ denote the n -step transition probabilities between the states (with $P_{(i,i)}^{(0)} = 1$); put differently, these are the n -step transition probabilities of the discrete-time Markov chain underlying the Markov process. The above formula is derived by conditioning on the number of transitions in $(0, t]$.

Equation (9) is computationally advantageous, as the infinite sum can be truncated while the $P_{ij}^{(n)}$ can be evaluated efficiently. An interesting idea, apparently

due to Jensen [7], allows extension of this principle to the case of *unequal* mean visit times. Let us assume that the mean visit time to state i is $1/\lambda_i$. Let λ be such that $\lambda \geq \lambda_i$ for all i . Consider a Poisson process with rate λ . Now consider a Markov process that spends $\exp(\lambda)$ in any state i and then jumps with probability $\hat{P}_{ij} = \frac{\lambda_i}{\lambda} P_{ij}$ to j and with

probability $\hat{P}_{ii} = 1 - \frac{\lambda_i}{\lambda}$ back to i ; one might call this a fictitious transition. Remember that a sum of a geometrically distributed number of independent exponentially distributed random variables is again exponentially distributed; hence the sum of consecutive visit times to state i , before another state is visited, is $\exp(\lambda_i)$. A little thought now shows that this new Markov process is really the same as the original Markov process. The transient behavior of the original Markov process can hence be inferred from that of the new Markov process, by using equation (9), with $P_{ij}^{(n)}$ being replaced by the n -step transition probabilities of the new discrete-time Markov chain that has transition probabilities $\hat{P}_{ij}$.

As an application of this uniformization technique, consider a system that alternates between up and down periods, up (down) periods being exponentially distributed with parameter μ_u (μ_d). We leave it to the reader to verify that by taking $\lambda = \mu_u + \mu_d$ as uniformization parameter, one gets new transition probabilities $\hat{P}_{uu} = \hat{P}_{du} = \frac{\mu_d}{\mu_u + \mu_d}$, and hence

$$\hat{P}_{uu}^{(n)} = \hat{P}_{du}^{(n)} = \frac{\mu_d}{\mu_u + \mu_d}, \quad n = 1, 2, \dots, \text{ leading to}$$

$$\begin{aligned} P(X(t) = u | X(0) = u) \\ = \frac{\mu_d}{\mu_u + \mu_d} + \frac{\mu_u}{\mu_u + \mu_d} e^{-(\mu_u + \mu_d)t} \end{aligned} \quad (10)$$

and by symmetry,

$$\begin{aligned} P(X(t) = d | X(0) = d) \\ = \frac{\mu_u}{\mu_u + \mu_d} + \frac{\mu_d}{\mu_u + \mu_d} e^{-(\mu_u + \mu_d)t} \end{aligned} \quad (11)$$

There is a large variety of other applications of the uniformization property in stochastic analysis and simulation, that may be found in various textbooks; the present example is taken from Ross [8, Section 5.8].

The Compound Poisson Process

A limitation of the Poisson process is that the jumps are always of unit size. A stochastic process $\{X(t), t \geq 0\}$ is called a *compound Poisson process* if it can be represented by

$$X(t) = \sum_{i=0}^{N(t)} Y_i, \quad t \geq 0 \quad (12)$$

where $\{N(t), t \geq 0\}$ is a Poisson process and $Y_1, Y_2, \dots$ are independent, identically distributed random variables that are also independent of $\{N(t), t \geq 0\}$. $X(t)$ could, for example, represent the accumulated workload input into a queuing system in $(0, t]$: Customers arrive according to a Poisson process $\{N(t), t \geq 0\}$, and the i th customer requires a service time of length Y_i . Alternatively, the Poisson arrival process might represent the number of insurance claims in $(0, t]$, while the Y_i represent independent claim sizes. $X(t)$ is then the total amount of monetary claims up to time t .

As another example one can envision a device subject to a series of independent random shocks. If the damage caused by the i th shock is Y_i and the number of shocks in $(0, t]$ is $N(t)$, then the total accumulated damage up to time t is given by $X(t)$.

It is easily seen that, if the rate of the Poisson process equals λ and the Y_i have a common Laplace–Stieltjes transform $\beta(s) = \mathbb{E}[e^{-sY_i}]$, then

$$\mathbb{E}[e^{-sX(t)}] = e^{-\lambda(1-\beta(s))t} \quad (13)$$

Differentiation then readily yields that $\mathbb{E}[X(t)] = \lambda t \mathbb{E}Y_1$ and $\text{Var}[X(t)] = \lambda t \mathbb{E}[Y_1^2]$.

Compound Poisson processes are an important subclass of Lévy processes (see **Lévy Processes**). We refer to Bertoin [9] for a detailed account of the theory of Lévy processes.

Epilogue

The Poisson process is a stochastic counting process that arises naturally in daily life situations in which

there is a large population of individuals who, more or less independently of each other, have a small probability of contributing to the count in the next small time interval. The (compound) Poisson process has beautiful mathematical properties, which make it a very powerful tool for stochastic modeling and analysis. We refer the interested reader to the monograph of Kingman [10]. Excellent textbook treatments can be found in the books of Ross [8] and Tijms [11].

Lévy Processes

Definitions and Assumptions

On a given probability space $(\Omega, \mathcal{F}, P)$, a continuous-time *stochastic process* is a collection of random variables $\{X_t | t \geq 0\}$. A Lévy process $\{X_t | t \geq 0\}$ is a continuous-time stochastic process having the following three properties:

1. $X_{t+s} - X_s$ is distributed like X_t for any nonnegative s and t .
2. For every integer $n \geq 2$ and $0 = t_0 < t_1 < \dots < t_n$, the random variables $\{X_{t_i} - X_{t_{i-1}} | 1 \leq i \leq n\}$ are independent.
3. $X_t \rightarrow 0$ in probability as $t \downarrow 0$.

Since for $0 < t < s$, $X_{t+s} - X_s$ and $X_s - X_{s-t}$ are distributed like X_t , it is clear that $X_{t+s} \rightarrow X_s$ and $X_{t-s} \rightarrow X_s$ in probability as $t \downarrow 0$ for any $s \geq 0$. Therefore, it is customary to refer to these three properties as 1: stationary increments, 2: independent increments, and 3: continuous in probability, respectively. Thus a Lévy process is a continuous-time stochastic process which has stationary, independent increments and is continuous in probability.

A more general definition of a Lévy process is as follows. Let $\{\mathcal{F}_t | t \geq 0\}$ be a nondecreasing family of σ algebras all of which are contained in $\mathcal{F}$. Such a family is called a *filtration*. In addition assume that the following two conditions are satisfied: (a) $\lim_{s \downarrow t} \mathcal{F}_s = \mathcal{F}_t$ and (b) $\mathcal{F}_0$ contains all the P null sets $\mathcal{F}$ (in particular, so does $\mathcal{F}$). Such a right continuous and augmented filtration is said to satisfy the *usual conditions* or is called a *standard filtration*. A Lévy process with respect to $\{\mathcal{F}_t | t \geq 0\}$ is a process satisfying the first and third condition above and where condition 2 is replaced by:

2. $X_{t+s} - X_t$ is independent of $\mathcal{F}_t$ for every $s, t \geq 0$.

It is easy to check that this condition implies that $\{X_t | t \geq 0\}$ has independent increments. Also, it can be shown that a Lévy process has a right continuous left limit (càdlàg) version, that is, there exists a càdlàg process $\{\tilde{X}_t | t \geq 0\}$ such that $P[\tilde{X}_t = X_t] = 1$ for each $t \geq 0$. It can be shown that the filtration generated by a right continuous process having

stationary independent increments is right continuous. A nice exposition of Lévy processes emphasizing such properties can be found in Section I.4 of [1]. See also [2], which has become a standard reference regarding Lévy processes.

Infinite Divisibility and Basic Structure

A random variable X has an infinitely divisible distribution if and only if for every $n \geq 2$ there are independent and identically distributed (i.i.d.) random variables, $X_1^{(n)}, \dots, X_n^{(n)}$, such that $\sum_{i=1}^n X_i^{(n)}$ is distributed like X . It is well known (e.g., Section 7.6 of [3] and Section 9.5 of [4]) that if X has an infinitely divisible distribution, then $Ee^{i\alpha X} = e^{\varphi(\alpha)}$, where, with A^c being the complement of a set A ,

$$\begin{aligned} \varphi(\alpha) = i\alpha c - \frac{\sigma^2 \alpha^2}{2} + \int_{[-1,1]^c} (e^{i\alpha x} - 1) \nu(dx) \\ + \int_{[-1,1]} (e^{i\alpha x} - 1 - i\alpha x) \nu(dx) \end{aligned} \quad (1)$$

and ν is a measure satisfying $\nu([-1,1]^c) < \infty$, $\int_{[-1,1]} x^2 \nu(dx) < \infty$, and $\nu(\{0\}) = 0$. The measure ν is called the *Lévy measure* and equation (1) is often referred to as the *Lévy–Khintchine formula*. It can be shown that for any measure satisfying these assumptions and for any c and σ^2 , there is an infinitely divisible distribution with a characteristic function having an exponent φ of this form. In fact, letting

$$I_n = \begin{cases} (n^{-1}, (n-1)^{-1}) & n = 2, 3, \dots \\ [n^{-1}, (n-1)^{-1}) & n = 2, 3, \dots \\ (1, \infty) & n = 1 \\ (-\infty, -1) & n = -1 \end{cases} \quad (2)$$

we set $\lambda_n = \nu(I_n)$, and when $\lambda_n > 0$, let $F_n(x) = \nu(I_n \cap (-\infty, x]) / \lambda_n$ (when $\lambda_n = 0$, F_n can be arbitrary). Let N_n be a Poisson random variable with mean λ_n and $X_k^{(n)}$ have distribution F_n . In addition, let Y be a normal random variable with mean c and variance σ^2 . Assume that all of these random variables are independent. Finally, let $S_0^{(n)} = 0$ and for $m \geq 1$, $S_m^{(n)} = \sum_{k=1}^m X_k^{(n)}$. Then,

$$Y + S_{N_1}^{(-1)} + S_{N_1}^1 + \sum_{\substack{n=-\infty \\ n \neq -1, 0, 1}}^{\infty} \left(S_{N_n}^{(n)} - \lambda_n E X_1^{(n)} \right) \quad (3)$$

2 Lévy Processes

has a distribution with the desired exponent and it can be shown that the infinite sum converges almost surely. Owing to this decomposition, it is easy to verify that when $\nu(-\infty, 0) = 0$, then E^{zX} is finite for every complex z with $\Re z \leq 0$ and is equal to $e^{\varphi(-iz)}$, where $\varphi(-iz)$ is the Lévy–Khintchine formula in which $i\alpha$ is replaced by z , that is,

$$\begin{aligned} \varphi(-iz) = & zc + \frac{\sigma^2 z^2}{2} + \int_{(1, \infty)} (e^{zx} - 1) \nu(dx) \\ & + \int_{(0, 1]} (e^{zx} - 1 - zx) \nu(dx) \end{aligned} \quad (4)$$

and in particular, for $\alpha \geq 0$ real,

$$\begin{aligned} \log Ee^{-\alpha X} = & -\alpha c + \frac{\sigma^2 \alpha^2}{2} + \int_{(1, \infty)} (e^{-\alpha x} - 1) \nu(dx) \\ & + \int_{(0, 1]} (e^{-\alpha x} - 1 + \alpha x) \nu(dx) \end{aligned} \quad (5)$$

Replacing Y by a **Brownian motion** $\{Y_t | t \geq 0\}$ and N_n by a **Poisson process** $\{N_n(t) | t \geq 0\}$ with rate λ_n , the resulting process is a Lévy process $\{X_t | t \geq 0\}$ satisfying $Ee^{i\alpha X_1} = e^{\varphi(\alpha)}$.

For a Lévy process $\{X_t | t \geq 0\}$, $X_t = \sum_{k=1}^n (X_{kt/n} - X_{(k-1)t/n})$, and thus by the stationary increments property, it follows that X_t has an infinite divisible distribution. In particular, if $Ee^{i\alpha X_t} = e^{\varphi(\alpha)t}$, then $Ee^{i\alpha X_t} = e^{\varphi(\alpha)t}$. φ is called the *characteristic exponent* (or just *exponent*) of the Lévy process. In particular, for any Lévy process, there is an exponent which satisfies the Lévy–Khintchine formula, and for any such exponent, there is a Lévy process having this exponent.

When $\int_{[-1, 1]} x \nu(dx) < \infty$, the non-Brownian part of the Lévy process almost surely has bounded variation sample paths; otherwise, it does not. In the case that it does, it is of the form $J_1(t) - J_2(t) + ct$, where J_1 and J_2 are independent nondecreasing pure jump Lévy processes. A nondecreasing Lévy process is called a *subordinator*. From the preceding, any subordinator is a finite or infinite sum of independent compound Poisson processes. It either has a finite number of jumps on any finite interval or an infinite number of jumps on any finite interval, but not both. An example of a subordinator with an infinite number of jumps on finite intervals is the gamma process, with $\nu(dx) = ae^{-bx}/x dx$. For this process, X_t has a gamma distribution,

that is, with density $\frac{b^{at}}{\Gamma(at)} e^{-bx} x^{at-1}$ for $x > 0$, and zero otherwise.

When $\nu(-\infty, 0) = 0$, the Lévy process has no negative jumps and for every complex z with $\Re z \leq 0$, $Ee^{zX_t} = e^{\varphi(-iz)t}$ and is finite. In particular, when $z = -\alpha$, where $\alpha \geq 0$ (real valued), we denote the Laplace–Stieltjes exponent by $\varphi_L(\alpha) = \varphi(i\alpha)$. It is easy to check that φ_L is a convex function which is differentiable on $(0, \infty)$ of all orders. In particular, if the Lévy process is not deterministic (necessarily a linear function), then φ_D is a strictly convex function. It also holds that φ_D is nonincreasing if and only if the Lévy process is a subordinator and that when the process is neither a subordinator nor deterministic then necessarily $\varphi_D(\alpha) \rightarrow \infty$ as $\alpha \rightarrow \infty$ and thus for every $\beta > 0$ there exists an $\alpha > 0$ for which $\varphi_D(\alpha) = \beta$. Let us denote this value by the function $\psi_D(\beta)$, that is, $\varphi_D(\psi_D(\beta)) = \beta$, so that ψ_D is an inverse function of φ_D when the domain of φ_D is $\{\alpha | \varphi_D(\alpha) > 0\}$ and the range is $(0, \infty)$. In this case, when $\varphi'_D(0) < 0$, there are two roots to the equation $\varphi_D(\alpha) = 0$ and when $\varphi'_D(0) \geq 0$ there is only one.

In general, it can be shown that if $\int_{[-1, 1]^c} |x| \nu(dx) < \infty$ then

$$EX_t/t = c + \int_{[-1, 1]^c} x \nu(dx) = -i\varphi'(0) \quad (6)$$

if $\int_{[-1, 1]^c} x^2 \nu(dx) < \infty$ then

$$\text{Var}(X_t)/t = \sigma^2 + \int_{(-\infty, \infty)} x^2 \nu(dx) = -\varphi''(0) \quad (7)$$

and if $\int_{[-1, 1]^c} |x|^n \nu(dx) < \infty$ for $n > 2$ then

$$(-i)^n \varphi^{(n)}(0) = \int_{(-\infty, \infty)} |x|^n \nu(dx) \quad (8)$$

There is a close relationship between Lévy processes and Poisson random measures. In particular, if $A_1, \dots, A_n$ are mutually disjoint Borel subsets of $[0, \infty) \times (-\infty, \infty)$, then if $N(A_i)$ counts the number of instances where $(t, \Delta X_t) \in A_i$, then $N(A_1), \dots, N(A_n)$ are independent Poisson random variables with $EN(A_i) = \nu(A_i)$. If the closure of A_i is disjoint from $[0, \infty) \times \{0\}$ and it is contained in $[0, t] \times (-\infty, \infty)$ for some $t < \infty$, then $\nu(A_i) < \infty$.

Martingales Associated with Lévy Processes

In this section, we consider a right continuous Lévy process $\{X_t | t \geq 0\}$ with respect to some filtration $\{\mathcal{F}_t | t \geq 0\}$ satisfying the usual conditions. The Wald martingale associated with $\{X_t | t \geq 0\}$ is the process $e^{i\alpha X_t - \varphi(\alpha)t}$. It is easy to check that this process is indeed a martingale. Similarly, for the case with no negative jumps $e^{-\alpha X_t - \varphi_L(\alpha)t}$ is a martingale for every $\alpha \geq 0$, and thus we have, for every $\beta > 0$, $e^{-\psi(\beta)X_t - \beta t}$ is also a martingale.

This last martingale can be used to show that for $T_x = \inf\{t | X_t < -x\}$ we have $Ee^{-\beta T_x} = e^{-\psi_D(\beta)x}$. $\{T_x | x \geq 0\}$ is in fact a subordinator with exponent $-\psi_D(\beta)$. Letting $\psi_D(0) = \psi_D(0+) = \lim_{\beta \downarrow 0} \psi_D(\beta)$, we have, if $\varphi'_D(0) \geq 0$ then $\psi_D(0) = 0$ and thus $P[T_x < \infty] = 1$, and if $\varphi'_D(0) < 0$ then $\psi_D(0) > 0$ and then $P[T_x < \infty] = e^{-\psi_D(0)x}$. In particular, this implies that $-\inf\{X_t | t \geq 0\}$ is exponentially distributed with rate $\varphi_D(0)$ as $T_x < \infty$ if and only if $-\inf\{X_t | t \geq 0\} > x$. If $S_x = \inf\{t | X_t = -x\}$, then it is an easy exercise to show that $P[S_x = T_x] = 1$, so that the same results hold with respect to S_x .

In [5], a useful martingale was established that has been used extensively in the literature. The results are as follows.

Theorem 1 *Let $\{X_t | t \geq 0\}$ be a Lévy process and let $\{Y_t | t \geq 0\}$ be right continuous with left limits. Denote $Y_{t-} = \lim_{s \uparrow t} Y_s$, $\Delta Y_t = Y_t - Y_{t-}$*

$$Y_t^c = Y_t - \sum_{0 < s \leq t} \Delta Y_s \quad (9)$$

Assume that $Y^c(\cdot)$ has bounded expected variation on compact intervals, that is, assume that it is a difference of two nonnegative, nondecreasing, continuous processes each having a finite expected value at each time epoch. Also assume that

$$E \sum_{0 < s \leq t} 1_{\{|\Delta Y_s| > 1\}} < \infty \quad (10)$$

and that

$$E \sum_{0 < s \leq t} |\Delta Y_s| 1_{\{|\Delta Y_s| \leq 1\}} < \infty \quad (11)$$

Finally, set $Z_t = X_t + Y_t$ (in particular, $Z_0 = Y_0$). Then the following is a zero mean martingale:

$$\begin{aligned} \varphi(\alpha) \int_0^t e^{i\alpha Z_s} ds + e^{i\alpha Z_0} - e^{i\alpha Z_t} + i\alpha \int_0^t e^{i\alpha Z_s} dY_s^c \\ + \sum_{0 < s \leq t} e^{i\alpha Z_s} (1 - e^{-i\alpha \Delta Y_s}) \end{aligned} \quad (12)$$

If in addition $\nu(-\infty, 0) = 0$ (no negative jumps) and $\{Z_t | t \geq 0\}$ is a nonnegative process, then the following is a zero mean martingale:

$$\begin{aligned} \varphi_L(\alpha) \int_0^t e^{-\alpha Z_s} ds + e^{-\alpha Z_0} - e^{-\alpha Z_t} - \alpha \int_0^t e^{-\alpha Z_s} dY_s^c \\ + \sum_{0 < s \leq t} e^{-\alpha Z_s} (1 - e^{\alpha \Delta Y_s}) \end{aligned} \quad (13)$$

It is noted that equations (10) and (11) are weaker than the condition

$$E \sum_{0 < s \leq t} 1_{\{|\Delta Y_s| > 0\}} < \infty \quad (14)$$

which is assumed in equation [5], but the results remain valid with this weaker condition. This martingale was successfully applied in a variety of models in queuing, storage models, and networks, risk, and finance.

Reflected Lévy Processes

A special case where the martingale of [5] applies is where $Y_t = z + L_t$, $z \geq 0$, and L_t is defined as follows.

1. $\{L_t | t \geq 0\}$ is nonnegative, nondecreasing, and right continuous.
2. $\{Z_t | t \geq 0\}$ is nonnegative.
3. One (and then all) of the following equivalent conditions holds (see [6]):
 - (a) For each $t \geq 0$, if $L_{t-} < L_s$ for $s > t$ then $Z_t = 0$.
 - (b) $\int_0^\infty Z_s dL_s = 0$.
 - (c) $\{L_t | t \geq 0\}$ is the minimal process satisfying 1 and 2.
 - (d) For each $t \geq 0$, $L_t = - \inf_{0 \leq s \leq t} \min(z + X_s, 0)$.

4 Lévy Processes

For this case $\{Z_t | t \geq 0\}$ is called a *reflected Lévy process*. When the Lévy process has no negative jumps, the process $\{Y_t | t \geq 0\}$ is continuous with $Y_0 = z$ and it can be verified that $EY_t < \infty$ for each $t \geq 0$. These properties together with the martingale in [5] can be used to show that

$$\varphi_L(\alpha) \int_0^t e^{-\alpha Z_s} ds + e^{-\alpha z} - e^{-\alpha Z_t} - \alpha L_t \quad (15)$$

is a zero mean martingale, which implies in a very simple way that if $EX_1 < 0$ then the distribution of Z_t converges in law to a distribution which has the following generalized Polachek–Khinchine formula (see [5] for details).

$$Ee^{-\alpha Z_\infty} = \frac{\alpha \varphi'_L(0)}{\varphi_L(\alpha)} \quad (16)$$

This result is well known and has also been proved by various other methods (e.g., see [7–9]). Recently, in [10], a class of martingales associated with a reflected Lévy process has been established, of which the martingale of [5] is a special case when applied to the reflected case.

The Wiener–Hopf Factorization

It is well known (e.g., [7, 10]) that the following decomposition holds. A similar decomposition holds for random walks. For every $q > 0$, there are two unique functions φ_q^+ and φ_q^- having the following properties:

1. φ_q^+ and φ_q^- are the characteristic functions of infinitely divisible laws.
2. φ_q^+ is analytic on $\{z | \Im(z) \geq 0\}$ and φ_q^- is analytic on $\{z | \Im(z) \leq 0\}$.
3. For every real α

$$\frac{q}{q + \varphi(\alpha)} = \varphi_q^+(\alpha) \varphi_q^-(\alpha) \quad (17)$$

Equation (17) is known as the celebrated *Wiener–Hopf factorization*. An interesting fact is that this result can be proved using the martingale from [5]. This is explicitly done in [10]. The Wiener–Hopf factorization has been used to prove various results about Lévy processes, the generalized Polachek–Khinchine formula, and results regarding first passage times in the same way that it has been applied to

random walks (e.g., [7]). Many of these results are now known to have independent martingale proofs.

Multidimensional Lévy Processes

An infinitely divisible distribution has a multivariate analog. In particular, it can be shown that a random vector has an infinitely divisible distribution if and only if it has a characteristic function of the form $e^{\varphi(\alpha)}$ where $\alpha \in \mathbb{R}^d$ and

$$\begin{aligned} \varphi(\alpha) = i\alpha^T c - \frac{1}{2}\alpha^T \Sigma \alpha + \int_{B^c} (e^{i\alpha^T x} - 1) \nu(dx) \\ + \int_B (e^{i\alpha^T x} - 1 - i\alpha^T x) \nu(dx) \end{aligned} \quad (18)$$

where B is a unit ball (open or closed), ν is a measure satisfying $\nu(B^c) < \infty$, $\int_B x^T x \nu(dx) < \infty$, and $\nu(\{0\}) = 0$, where T means transposition and α , x , and c are in $\mathbb{R}^d$. B can be replaced by other bounded sets like $[-1, 1]^d$, of which the interior contains the origin.

If $\{X_t | t \geq 0\}$ is a multidimensional Lévy process, then for every $\alpha \in \mathbb{R}^d$, $\{\alpha^T X_t | t \geq 0\}$ is a one-dimensional Lévy process with exponent $\varphi^*(\beta) = \varphi(\beta\alpha)$. In particular, inserting $\beta = 1$ immediately implies that the martingale result of [5] applies without change in the multivariate case, that is, one simply replaces α by α^T in equations (12) and (13), and assumes that each coordinate of Y^c has bounded expected variation on finite intervals and that

$$E \sum_{0 < s \leq t} 1_{\{\|\Delta Y_s\| > 1\}} < \infty \quad (19)$$

and that

$$E \sum_{0 < s \leq t} \|\Delta Y_s\| 1_{\{\|\Delta Y_s\| \leq 1\}} < \infty \quad (20)$$

where $\|x\| = \sqrt{x^T x}$. The last assumption is to assure that

$$E \left| \sum_{0 < s \leq t} e^{i\alpha^T Z_s} (1 - e^{-i\alpha^T \Delta Y_s}) \right| < \infty \quad (21)$$

and the same for the case where the Lévy process has no negative jumps and the coordinates of α are nonnegative.

Multidimensional Reflected Lévy Process

If $\{X_t | t \geq 0\}$ is a multidimensional Lévy process and $A = (a_{ij})$ is a nonnegative matrix with spectral radius less than 1 (i.e., $A^n \rightarrow 0$ as $n \rightarrow \infty$), then $Z_t = z + X_t + (I - A)L_t$ is a multidimensional reflected Lévy process if the following are satisfied.

1. Each coordinate of $\{L_t | t \geq 0\}$ is nonnegative, nondecreasing, and right continuous.
2. Each coordinate of $\{Z_t | t \geq 0\}$ is nonnegative.
3. One (and then all) of the following equivalent conditions holds (see [6]):
 - (a) For each i and each $t \geq 0$, if $L_{t-}^i < L_s^i$ for $s > t$ then $Z_t^i = 0$.
 - (b) For each i , $\int_0^\infty Z_s^i dL_s^i = 0$.
 - (c) $\{L_t | t \geq 0\}$ is the minimal process satisfying 1 and 2.
 - (d) $\{L_t | t \geq 0\}$ is the unique process such that for each $t \geq 0$,

$$L_t^i = - \inf_{0 \leq s \leq t} \min \left(z + X_s^i - \sum_j a_{ij} L_s^j, 0 \right) \quad (22)$$

See, for example, Lemma 14.2.6 in [11].

For the case where the Lévy process is a Brownian motion, this process is an instance of a Brownian network and has been shown, under various conditions, to be the weak limit of general Jackson-type queueing networks, that is, a network of **queues** where customers upon completion of service in a given station are routed to another station or out of the network according to some lottery which is independent of the past and can change from station to station (Markovian routing). The literature related to this is vast. The earliest general result seems to be [12] and a recent one is [13] which contains an impressive bibliography.

Another application is a fluid network with Lévy input. In this model, a content which is referred to as *fluid* arrives at the various stations of the network according to a nondecreasing multidimensional Lévy process $\{J_t | t \geq 0\}$. Each station has a maximal processing rate r_i and processes fluid at the maximal rate whenever its buffer content is not zero. A fixed proportion p_{ij} of each unit of processed fluid is instantly transferred from station i to station j . It can be shown that such a model is a special case of a multidimensional reflected Lévy process with

$A = P^T$ and $X_t = J_t - (I - A)rt$. This model, under various assumptions, has been considered in the literature. For a recent reference with a rather complete set of bibliography to related literature, see [14].

Markov Additive Processes and Associated Martingales

A generalization of a Lévy process is the *Markov additive process*. See [15]. This is more or less a Lévy process subject to a Markovian random environment. When the Markovian environment changes according to a right continuous, continuous-time, finite state space Markov chain $\{E_t | t \geq 0\}$, this process has a more explicit representation.

Let $\{1, \dots, K\}$ be the states and let $\{X^i | 1 \leq i \leq K\}$ be independent right continuous Lévy processes, that is, having stationary increments with $X^i(t) - X^i(s)$ being independent of $\mathcal{F}_s$ for every $0 \leq s < t$, with $X^i(0) = 0$, each having an exponent $\varphi_i(\alpha) = \log(Ee^{i\alpha X_1})$. Assume that $\{E_t | t \geq 0\}$ is independent of $X^1, \dots, X^K$. In addition, let $\{U_n^{ij} | n \geq 1, 1 \leq i, j \leq K\}$ be independent random variables, which are also independent of $X^1, \dots, X^K$, $\{E_t | t \geq 0\}$, and $\mathcal{F}_0$, such that for every i, j, n , $\{U_n^{ij} | n \geq 1\}$ are identically distributed. We assume that $U_{ii}^{ij} \equiv 0$. Letting $\{T_i | i \geq 0\}$ be the jump epochs of $\{E_t | t \geq 0\}$ (with $T_0 = 0$), it is assumed that for every i, j, n , U_n^{ij} is $\mathcal{F}_{T_n}$ measurable. Then the Markov additive process has the following representation.

$$\begin{aligned} X_t = X_0 + \sum_{n \geq 1} \sum_{1 \leq i, j \leq K, i \neq j} (X_{T_n}^i - X_{T_{n-1}}^i + U_n^{ij}) \\ \times 1_{\{E_{T_{n-1}} = i, E_{T_n} = j, T_n \leq t\}} + \sum_{n \geq 1} \sum_{1 \leq i \leq K} (X_t^i - X_{T_{n-1}}^i) \\ \times 1_{\{E_{T_{n-1}} = i, T_{n-1} \leq t < T_n\}} \end{aligned} \quad (23)$$

where $X_0 \in \mathcal{F}_0$.

Let Q be the infinitesimal transition matrix of $\{E_t | t \geq 0\}$, $G_{ij}(\alpha)$ be the characteristic function of U_n^{ij} and $\mathbf{1}_j$ be a row vector where the j th coordinate is one and the rest are zero. Finally let $F(\alpha) = (F_{ij}(\alpha))$,

$$F_{ij}(\alpha) = q_{ij}G_{ij}(\alpha) + \varphi_i(\alpha)\delta_{ij} \quad (24)$$

where $\delta_{ii} = 1$ and $\delta_{ij} = 0$, when $i \neq j$.

In [16], the following results are shown and various applications are discussed. Note that for a

matrix A , e^A is the matrix exponential associated with A , that is, $e^A = \sum_{n=0}^{\infty} \frac{1}{n!} A^n$.

Lemma 1 *For any initial distribution of (X_0, E_0) and every real α ,*

$$M^W(t, \alpha) = e^{i\alpha X_t} \mathbf{1}_{E_t} e^{-F(\alpha)t} \quad (25)$$

is a (row) vector-valued martingale. Consequently, if $h(\alpha)$ and $\lambda(\alpha)$ are a right eigenvector and eigenvalue of the matrix $F(\alpha)$, then with every initial distribution of (X_0, E_0)

$$e^{i\alpha X_t - \lambda(\alpha)t} h_{E_t}(\alpha) \quad (26)$$

is a martingale.

For the next theorem, we extend the definition of $F(\alpha)$ to the appropriate part of the complex plane (as discussed in the theorem) and we denote $\tilde{F}(\alpha) = F(-i\alpha)$ for complex α .

Theorem 2 *Let $Y = \{Y_t | t \geq 0\}$ be an adapted continuous process having a finite expected variation on compact intervals. Set $Z_t = X_t + Y_t$ and assume either of the following conditions:*

1. X^i have no negative jumps, U_{ij} are nonnegative, $Z = \{Z_t | t \geq 0\}$ is a nonnegative process and $\Re(\alpha) \leq 0$,
2. X^i have no positive jumps, U_{ij} are nonpositive, Z is nonpositive and $\Re(\alpha) \geq 0$,
3. $\Re(\alpha) = 0$,
4. X^i are Brownian motions or linear and U_{ij} are zero (α is unrestricted).

Then, for every initial distribution of (X_0, E_0) ,

$$\begin{aligned} M(\alpha, t) = & \int_0^t e^{\alpha Z_s} \mathbf{1}_{E_s} ds \tilde{F}(\alpha) + e^{\alpha Z_0} \mathbf{1}_{E_0} - e^{\alpha Z_t} \mathbf{1}_{E_t} \\ & + \alpha \int_0^t e^{\alpha Z_s} \mathbf{1}_{E_s} dY_s \end{aligned} \quad (27)$$

is a (row) vector-valued, zero mean martingale. Consequently, with $\lambda(\alpha)$ and $h(\alpha)$ as in Lemma 1

$$\begin{aligned} \lambda(\alpha) \int_0^t e^{\alpha Z_s} h_{E_s}(\alpha) ds + e^{\alpha Z_0} h_{E_0}(\alpha) - e^{\alpha Z_t} h_{E_t}(\alpha) \\ + \alpha \int_0^t e^{\alpha Z_s} h_{E_s}(\alpha) dY_s \end{aligned} \quad (28)$$

is a zero mean martingale.

Markov Processes

Basic Definitions

A *Markov process* (MP) is a stochastic process $(X_t)_{t \in T}$ (where usually $T = \mathbb{Z}_+$ or $T = \mathbb{R}_+$) with values in some state space S that has the *Markov property*: for any $n \in \mathbb{N}$, time indices $t_1 < \dots < t_n < t$ and states $x_1, \dots, x_n \in S$ the conditional distribution of X_t given that $X_{t_1} = x_1, \dots, X_{t_n} = x_n$ coincides with that under the condition $X_{t_n} = x_n$. In other words, the probability law of the evolution of X_t after any fixed time instant s depends on its past only through the value of X_s , so that the “present state” contains all the relevant information about the future. The Markov property is equivalent to the following conditional independence property. Let $\mathcal{F}_s$ and $\mathcal{F}$ be the σ -algebras generated by $(X_t)_{t \leq s}$ and $(X_t)_{t \geq s}$, describing the past up to time s and the future starting at s , respectively. Then for all s and events $A \in \mathcal{F}_s$ and $B \in \mathcal{F}$,

$$\mathbb{P}(A \cap B \mid X_s) = \mathbb{P}(A \mid X_s) \mathbb{P}(B \mid X_s) \quad (1)$$

Depending on whether the time index set T and the state space S are discrete or continuous, one can distinguish four types of MPs. We will for simplicity only consider Borel subsets $S \subset \mathbb{R}$ and the time ranges $T = \mathbb{R}_+$ or $T = \mathbb{Z}_+$. If either the state space or the time range or both are countable, one also uses the term *Markov chain*.

The feature that the future development depends on the past only through the current state lies behind the ubiquitous occurrence of MPs in applied probability. It is analogous to the well-known property of deterministic dynamical systems that the solution of their motion equations are uniquely determined by the data (i.e., the positions and velocities of the particles involved) at one time instant. Arguably most stochastic models for real-life systems are based on underlying MPs. Important classes of MPs are random walks, birth-and-death processes, many of the processes occurring in classical queuing, dam, storage and reliability theory, Lévy processes (e.g., compound Poisson processes and **Brownian motion**), and diffusions. In this article we can give only a condensed survey of the basic mathematical machinery for the analysis of MPs. In the section titled “Discrete-Time Markov Processes” we deal with a case of discrete

time, describing in particular the classical theory for countable state space and the main results for Harris chains. The section titled “Continuous-Time Markov Processes” is devoted to the basics of the continuous-time case. In the section titled “Example: The Performance of a Replacement Policy” we present the computation of performance measures of a replacement policy in a concrete model of a failure system; this is meant as an example to show the general techniques at work. Finally, in the section titled “Continuous-Time MPs with Countable State Space” we discuss the basic constructions and analysis of continuous-time MPs with countable state space.

Among the many excellent monographs and textbooks on different levels we mention [1–4] for the general theory of MPs and [5–8] for an in-depth analysis of Markov chains with a view toward applications. See also [9, 10] for the case of discrete state space and [11] for Harris chains. We do not discuss Lévy processes [12, 13], Brownian motion [4, 14] or diffusions [1, 2, 15]. The example in the section titled “Example: The Performance of a Replacement Policy” is taken from [16]. We start with the case of discrete time.

Discrete-Time Markov Processes

If $T = \mathbb{Z}_+$, the Markov property can be formulated as

$$\mathbb{P}(X_{n+1} \in B \mid X_0, \dots, X_n) = \mathbb{P}(X_{n+1} \in B \mid X_n) \quad \text{almost surely} \quad (2)$$

for all $n \in \mathbb{Z}_+$ and all $B \in \mathcal{B}(S)$ (the Borel σ -algebra in S). For every n one can choose a stochastic kernel $p_n(x, B)$ which is a version of $\mathbb{P}(X_{n+1} \in B \mid X_n = x)$. These kernels give the *transition probabilities* of the MP. Together with the *initial distribution*,

$$\pi(B) = \mathbb{P}(X_0 \in B) \quad (3)$$

they determine the finite-dimensional distributions and thus the law of the MP: one can show that for all n and $B_0, \dots, B_n \in \mathcal{B}(S)$,

$$\begin{aligned} \mathbb{P}(X_0 \in B_0, \dots, X_n \in B_n) &= \int_{B_{n-1}} \dots \int_{B_0} \\ &\times p_{n-1}(x_{n-1}, B_{n-1}) p_{n-2}(x_{n-2}, dx_{n-1}) \\ &\dots p_0(x_0, dx_1) \pi(dx_0) \end{aligned} \quad (4)$$

2 Markov Processes

Conversely, for any sequence $p_n(x, B)$, $n \in \mathbb{Z}_+$, of stochastic kernels and any distribution π on S one can construct an MP on the infinite product space $(S^{\mathbb{N}}, \mathcal{B}(S)^{\mathbb{N}})$ of countably many factors $(S, \mathcal{B}(S))$ with the X_n s being the coordinate mappings, having the $p_n(x, B)$ as transition probabilities and π as distribution of X_0 . Let $\mathbb{P}_\pi$ and $\mathbb{E}_\pi$ be the corresponding probability measure on $(S^{\mathbb{N}}, \mathcal{B}(S)^{\mathbb{N}})$ and expectation, respectively. This standard measure theoretic construction allows to consider simultaneously a whole collection of MPs having the same transition probabilities but variable initial distributions. If π is the point mass at some x , we write $\mathbb{P}_\pi = \mathbb{P}_x$ and $\mathbb{E}_\pi = \mathbb{E}_x$ and speak of the MP starting from the point x .

In the following we will restrict ourselves to the case when $p(x, B) = p_n(x, B)$ can be chosen independently of n so that the time index n can be omitted. The MP is then called *homogeneous*; $p(x, B)$ is the probability of going from x to B in one step. For homogeneous MPs equation (2) takes the form

$$\mathbb{P}_\pi(X_{n+1} \in B \mid X_0, \dots, X_n) = \mathbb{P}_{X_n}(X_1 \in B) \quad \mathbb{P}_\pi\text{-almost surely} \quad (5)$$

For homogeneous discrete-time MPs a generalization of their defining property (5) from deterministic times n to certain nonanticipatory random times, the so-called *strong Markov property*, holds. A *stopping time* is a random variable with values in $\mathbb{Z}_+ \cup \{\infty\}$ for which $\{\tau = n\} \in \sigma(X_0, \dots, X_n)$ (the σ -algebra generated by $X_0, \dots, X_n$) for all $n \in \mathbb{Z}_+$. Then $\mathcal{F}_\tau$ is defined to be the set of all events A for which $A \cap \{\tau = n\} \in \sigma(X_0, \dots, X_n)$ for all $n \in \mathbb{Z}_+$; $\mathcal{F}_\tau$ is the σ -algebra consisting of all events whose occurrence or nonoccurrence is known at time τ . If $\tau < \infty$, the MP is at state X_τ at time τ . The strong Markov property states that the evolution of the process after time τ is conditionally independent of $\mathcal{F}_\tau$, given X_τ , and follows the same law as the process started at the state X_τ . Formally,

$$\mathbb{P}_\pi((X_\tau, X_{\tau+1}, \dots) \in C \mid \mathcal{F}_\tau) = \mathbb{P}_{X_\tau}((X_0, X_1, \dots) \in C) \quad \mathbb{P}_\pi\text{-almost surely on } \{\tau < \infty\} \text{ for every } C \in \mathcal{B}(S)^{\mathbb{N}} \quad (6)$$

For example, the strong Markov property is basic for studying the recurrence behavior of MPs, because

it implies that following any visit to some state the process behaves as if starting anew from this state.

An MP is called *asymptotically stationary* if there is a stationary process $(Y_n)_{n \in \mathbb{Z}_+}$ such that the joint distribution of the tail sequence $(X_{k+n})_{n \in \mathbb{Z}_+}$ converges to that of $(Y_n)_{n \in \mathbb{Z}_+}$ in the sense that

$$\lim_{k \rightarrow \infty} \mathbb{P}_\pi((X_{k+n})_{n \in \mathbb{Z}_+} \in C) = \mathbb{P}((Y_n)_{n \in \mathbb{Z}_+} \in C) \quad \text{for all } C \in \mathcal{B}(S)^\infty \quad (7)$$

under any initial distribution π , as $k \rightarrow \infty$. To prove asymptotic stationarity, it turns out to be sufficient to show a one-dimensional convergence result. A probability measure ρ on the state space is called *stationary initial distribution* (s.i.d.) if

$$\rho(B) = \int_S p(x, B) d\rho(x) \quad \text{for all } B \in \mathcal{B}(S) \quad (8)$$

If an MP has an s.i.d. ρ , then it is a stationary process under $\mathbb{P}_\rho$, and if it can be shown that for some probability measure ρ , $\mathbb{P}_x(X_n \in B)$ converges to $\rho(B)$ for all x and B , then the MP is asymptotically stationary (the limit being $(X_n)_{n \in \mathbb{Z}_+}$ under $\mathbb{P}_\rho$). There is at most one s.i.d. if the MP is not decomposable, i.e., if the state space cannot be partitioned into two disjoint sets A_1, A_2 such that $p(x, A_i) = 1$ for all $x \in A_i$, $i = 1, 2$. If an s.i.d. ρ exists, one can show that equation (7) holds with limit $\mathbb{P}_\rho((X_n)_{n \in \mathbb{Z}_+} \in \cdot)$ if

1. for every $n = 1, 2, \dots$, indecomposability holds under all transition probabilities $p^{(n)}(x, B) = P_x(X_n \in B)$, and
2. the distribution $p(x, \cdot)$ is absolutely continuous with respect to ρ for every x .

In general the problems of the existence of an s.i.d. and of asymptotic stationarity are difficult. A complete solution can be given for countable state spaces, whereas for uncountable state spaces there is the theory of Harris chains. We will now discuss these two special cases.

Countable State Space

In this subsection we take S to be a subset of the integers. The transition probabilities can then be represented as a matrix $P = (p_{ij})_{i,j \in S}$, where $p_{ij} = p(i, \{j\})$, whereas the initial distribution becomes a vector $\pi = (\mathbb{P}(X_0 = i))_{i \in S}$. The *n-step transition*

probabilities $p_{ij}^{(n)} = \mathbb{P}(X_n = j \mid X_0 = i)$ satisfy the Chapman–Kolmogorov equations

$$p_{ij}^{(n+1)} = \sum_{k \in S} p_{ik}^{(n)} p_{kj} \quad (9)$$

This means that the matrix $p_{ij}^{(n)}$ is just the n th power P^n of the transition matrix P . Thus, the stationarity and asymptotics of MPs can be tackled by studying the limiting behavior of the powers of stochastic matrices. If the state space is finite, this is a classical topic in matrix theory. In the general countable case one has to study the sequences of visits of the MP to its states because by the strong Markov property at each time a state i is visited, the MP restarts anew from i independently of the past.

A state i is called *recurrent* if $\mathbb{P}_i(X_n = i \text{ for some } n \geq 1) = 1$ and *transient* otherwise. Let N_i denote the number of visits in i . It can be shown that i is recurrent if and only if $\mathbb{P}_i(N_i < \infty) = 0$, which in turn is equivalent to

$$\mathbb{E}_i(N_i) = \sum_{n=1}^{\infty} p_{ii}^{(n)} = \infty \quad (10)$$

If i is recurrent, the $(\mathbb{P}_i$ -almost surely nonterminating) sequence of times of visits in i forms a renewal process, i.e., the times between visits are i.i.d. random variables. Let $\tau_i = \inf\{n \geq 1 \mid X_n = i\}$ be the time of the first visit of i (with $\inf \emptyset = \infty$). i is called *positive recurrent* if $\mathbb{E}_i(\tau_i) < \infty$, and *null recurrent* if $\mathbb{E}_i(\tau_i) = \infty$. The largest integer d for which $\mathbb{P}_i(\tau_i \in \{d, 2d, 3d, \dots\}) = 1$ is called the *period* of i , and if the period is 1, i is called *aperiodic*. Two states i and j are said to *communicate* if there are integers $n, m \geq 1$ such that $p_{ij}^{(n)} > 0$ and $p_{ji}^{(m)} > 0$. If two states communicate, they have the same period and are simultaneously either positive recurrent, or null recurrent, or transient. On the set R of recurrent states communication is an equivalence relation, so that R consists of disjoint communication classes. The states in one class have the same period d , and if $d > 1$ the class can be split into disjoint “periodic” subsets $C_1, \dots, C_d$ such that for any state $i \in C_l$ the next transition goes to some state in C_{l+1} (where $C_{d+1} = C_1$). Finally, an MP is called *irreducible* if all states communicate with each other.

On the basis of these classifications of the states a complete description of the asymptotic behavior of

the transition probabilities can be given. First, let us call a measure $\rho = (\rho_j)_{j \in S}$ *stationary* if $0 \leq \rho_j < \infty$ and $\rho_j = \sum_{i \in S} \rho_i p_{ij}$ for all $j \in S$. For any fixed recurrent state i one can define a stationary measure by setting ρ_j equal to the expected number of visits of j between two consecutive visits of i . If X_n is irreducible and recurrent, this ρ is the only stationary measure up to a multiplicative constant and $\rho_j > 0$ for all j . In particular, if we additionally assume positive recurrence, there is exactly one stationary distribution π , and it is given by $\pi_j = 1/\mathbb{E}_j(\tau_j)$. Now let us look at the limiting behavior of $p_{ij}^{(n)}$.

1. Let j be null recurrent or transient. Then $\lim_{n \rightarrow \infty} p_{ij}^{(n)} = 0$ for every state i .
2. Let j be positive recurrent with period d , and let i communicate with j . Then if $p_{ij}^{(nd+l)} > 0$ for some $n \geq 0$ and $l \in \{1, \dots, d\}$, we have $p_{ij}^{(N)} = 0$ for $N \not\equiv l \pmod{d}$ and $\lim_{n \rightarrow \infty} p_{ij}^{(nd+l)} = d/\mathbb{E}_j(\tau_j)$.
3. If j is positive recurrent and $p_{ij}^{(n)} > 0$ for some n , then either i and j communicate (so that we are in case (2)), or i is transient. Let i be transient. Then if j is aperiodic, $\lim_{n \rightarrow \infty} p_{ij}^{(n)} = r(i)/\mathbb{E}_j(\tau_j)$, where $r(i) = \mathbb{P}_i(X_n = j \text{ for some } n)$. If j has period $d > 1$ the limiting behavior depends on which (if any) of the periodic subsets $C_1, \dots, C_d$ of the communication class C of j is entered first after the start from i , and after how many steps this happens. Let $\sigma_j = \inf\{n \geq 1 \mid X_n \in C\}$. Then for all $N \geq 1$ and $l \in \{1, \dots, d\}$,

$$\begin{aligned} \lim_{n \rightarrow \infty} \mathbb{P}_i(X_{N+l+nd} = j \mid \sigma_j = N, X_{\sigma_j} \in C_{d-l+1}) \\ = d/\mathbb{E}_j(\tau_j) \end{aligned} \quad (11)$$

$$\begin{aligned} \mathbb{P}_i(X_{N+l+nd} = j \mid \sigma_j = N, X_{\sigma_j} \in C_{d-l+1}) \\ = 0 \text{ if } n \not\equiv N+l \pmod{d} \end{aligned} \quad (12)$$

The limiting behavior of $p_{ij}^{(n)}$ is then obtained by deconditioning with respect to the pair (σ_j, X_{σ_j}) .

The main result in this description is the ergodic theorem for discrete-time MPs. If X_n is irreducible, aperiodic and positive recurrent, then

$$\lim_{n \rightarrow \infty} p_{ij}^{(n)} = 1/\mathbb{E}_j(\tau_j) = \pi_j \text{ for all } i, j \in S \quad (13)$$

Note that the limit is the stationary distribution of X_n . Actually, a stronger result is valid: if all states

4 Markov Processes

communicate, are aperiodic and recurrent, we have

$$\lim_{n \rightarrow \infty} \sum_{j \in I} |\mathbb{P}_i(X_n = j) - \mathbb{P}_k(X_n = j)| = 0$$

for all $i, k \in S$ (14)

Equation (13) follows from equation (14) because for any fixed states $i, j_0 \in S$

$$\begin{aligned} 0 &= \lim_{n \rightarrow \infty} \sum_{k \in I} \pi_k \sum_{j \in I} |\mathbb{P}_i(X_n = j) - \mathbb{P}_k(X_n = j)| \\ &\geq \lim_{n \rightarrow \infty} \sum_{k \in I} \pi_k |\mathbb{P}_i(X_n = j_0) - \mathbb{P}_k(X_n = j_0)| \\ &\geq \lim_{n \rightarrow \infty} \left| \sum_{k \in I} \left(\pi_k \mathbb{P}_i(X_n = j_0) - \pi_k \mathbb{P}_k(X_n = j_0) \right) \right| \\ &= \lim_{n \rightarrow \infty} |\mathbb{P}_i(X_n = j_0) - \mathbb{P}_\pi(X_n = j_0)| \\ &= \lim_{n \rightarrow \infty} |p_{ij_0}^{(n)} - \pi_{j_0}| \end{aligned} \quad (15)$$

Continuous State Space

For a discrete-time MP X_n with state space $\mathbb{R}$ there is in most cases no simple regeneration structure, since single states are usually not revisited with positive probability. Thus one has to consider visits to subsets $R \subset \mathbb{R}$: we call R *recurrent* if $\tau_R = \inf\{n \in \mathbb{N} \mid X_n \in R\}$ satisfies $\mathbb{P}_x(\tau_R < \infty) = 1$ for all $x \in R$. A recurrent set R is said to be a *regeneration set* if for some $n \in \mathbb{N}$ the n -step transition probability measures $p^{(n)}(x, \cdot) = \mathbb{P}_x(X_n \in \cdot)$, $x \in R$, share some component, i.e., if there is an $n_0 \in \mathbb{N}$, a probability measure μ on the state space and an $\varepsilon > 0$ such that

$$p^{(n_0)}(x, \cdot) \geq \varepsilon \mu(\cdot) \quad \text{for all } x \in R \quad (16)$$

If X_n possesses a regeneration set, it is called a *Harris chain*. For given transition probabilities with a regeneration set R we can construct a corresponding Harris chain with an embedded regenerative structure as follows. First take the standard version of the MP from an arbitrary initial state x until time τ_R when R is visited for the first time. Then define $X_{\tau_R+n_0}$ by **randomization**: take a random variable which has either distribution μ with probability ε or distribution $(1 - \varepsilon)^{-1}[p^{(n_0)}(X_{\tau_R}, \cdot) - \varepsilon \mu(\cdot)]$ with probability $1 - \varepsilon$. Next, construct the missing part

$(X_{\tau_R+n})_{0 < n < n_0}$, according to the conditional distribution of $(X_n)_{0 < n < n_0}$, given that the pair of “boundary values” (X_0, X_{n_0}) is equal to the pair of values obtained before for X_{τ_R} and $X_{\tau_R+n_0}$. Finally, continue the construction from the new “initial” value $X_{\tau_R+n_0}$, and so on. The process constructed this way is an MP with transition probability measures $p(x, \cdot)$ which, due to the randomization, has distribution μ with probability ε n_0 steps after any visit to R . Let us start this MP with μ as initial distribution for X_0 . The times between two consecutive recurrences of the distribution μ obtained by the randomizations are called *cycles*.

Using this cycle decomposition, the following results can be proved for Harris chains:

1. There is exactly one stationary measure up to a positive factor; this measure ρ can be defined by setting $\rho(A)$ equal to the expected number of visits to A during a cycle started with initial distribution μ .
2. X_n is called *aperiodic* if the distribution of the length of a cycle started with μ is aperiodic. It is called *positive recurrent (null recurrent)* if the stationary measure has finite (infinite) total mass. For an aperiodic, positive recurrent Harris chain $p^{(n)}(x, \cdot)$ converges to the stationary probability measure in total variation.

For an aperiodic, null recurrent Harris chain, $\lim_{n \rightarrow \infty} p^{(n)}(x, B) = 0$ for all x and all Borel sets B with finite stationary measure.

Continuous-Time Markov Processes

In the case $T = \mathbb{R}_+$, $S \subset \mathbb{R}$ the Markov property reads as

$$\mathbb{P}(X_{t+s} \in B \mid (X_u)_{u \in [0, t]}) = \mathbb{P}(X_{t+s} \in B \mid X_t)$$

$\mathbb{P}$ -almost surely for all $t, s \geq 0$, $B \in \mathcal{B}(S)$ (17)

For all $t > s \geq 0$ one can choose a stochastic kernel $p_{s,t}(x, B)$ which is a version of $\mathbb{P}(X_t \in B \mid X_s = x)$. These kernels give the *transition probabilities* of the MP. Together with the *initial distribution*,

$$\pi(B) = \mathbb{P}(X_0 \in B) \quad (18)$$

they determine the finite-dimensional distributions and thus the law of the MP: one can show that for

all n , $0 \leq t_0 < t_1 < \dots < t_n$ and $B_0, \dots, B_n \in \mathcal{B}(S)$,

$$\begin{aligned} \mathbb{P}(X_{t_0} \in B_0, \dots, X_{t_n} \in B_n) &= \int_{B_{n-1}} \dots \int_{B_0} \\ &\times p_{t_{n-1}, t_n}(x_{n-1}, dx_n) p_{t_{n-2}, t_{n-1}}(x_{n-2}, dx_{n-1}) \\ &\dots p_{t_0, t_1}(x_0, dx_1) \pi(dx_0) \end{aligned} \quad (19)$$

The Chapman–Kolmogorov equations hold in the form

$$p_{t_0, t_1}(x, B) = \int_S p_{s, t_1}(y, B) p_{t_0, s}(x, dy) \quad (20)$$

almost surely with respect to the distribution of X_{t_0} for all $t_1 > s > t_0 \geq 0$.

Usually, the transition probabilities and the initial distribution of an MP are specified, and one wants to study the properties of an MP in these terms. Suppose a probability measure π on S and a collection of stochastic kernels $p_{s, t}(x, B)$, $t > s \geq 0$, are given. The kernels are assumed to satisfy equation (20) for all $x \in S$, $B \in \mathcal{B}(S)$ and all $t_1 > s > t_0 \geq 0$. Then one can show that the finite-dimensional distributions defined by equation (19) are consistent, so that they uniquely determine a probability measure on the product space $(S^{[0, \infty)}, \mathcal{B}(S)^{[0, \infty)})$ such that its coordinate mappings X_t form an MP having the functions $p_{s, t}(x, B)$ as transition probabilities and π as distribution of X_0 . Thus the only requirement to create an MP from transition kernels is that they satisfy the Chapman–Kolmogorov equations identically.

From now on we will again only consider homogeneous MPs: these are MPs whose transition probabilities satisfy

$$p_{s, t}(x, B) = p_{0, t-s}(x, B) \quad \text{for all } t > s \geq 0 \quad (21)$$

We write $p_t(x, B) = p_{0, t}(x, B)$. The Chapman–Kolmogorov equations now take the form

$$p_{t+s}(x, B) = \int_S p_s(y, B) p_t(x, dy) \quad (22)$$

for all $t, s > 0$ and all x and B . In the following all conditional probabilities and expectations are assumed to be obtained from the $p_t(x, B)$.

Let $\mathbb{P}_\pi$ and $\mathbb{E}_\pi$ be the corresponding probability measure and expectation on $(S^{[0, \infty)}, \mathcal{B}(S)^{[0, \infty)})$ constructed from the $p_t(x, B)$ and the initial distribution π . If π is the point mass at some x , we write

$\mathbb{P}_\pi = \mathbb{P}_x$ and $\mathbb{E}_\pi = \mathbb{E}_x$ and speak of the MP starting from the point x . We now consider only this coordinate representation process (so that the measurability of sets and functions will not depend on the selection of a starting point) simultaneously for variable initial distributions.

By equation (22), the transition probabilities $p_t(x, B)$ are completely determined for all $t > 0$ by their values for t in an arbitrarily small time interval $(0, \varepsilon)$, $\varepsilon > 0$. Thus it seems that the distribution of an MP can be specified by their infinitesimal behavior at zero. From now on we only consider MPs for which $p_t(x, (x - \varepsilon, x + \varepsilon)) \rightarrow 1$ for all $\varepsilon > 0$ as $t \rightarrow 0$, i.e., $X_t \rightarrow X_0$ in probability. The *generator* of an MP is defined to be the operator $\mathcal{G}$, given by

$$(\mathcal{G}f)(x) = \lim_{t \rightarrow 0} t^{-1} [\mathbb{E}_x(f(X_t)) - f(x)] \quad (23)$$

whose domain $D_{\mathcal{G}}$ is the set of all bounded measurable functions f on S for which the limit in equation (23) exists for all $x \in S$. For example, if X_t is a compound **Poisson process** with rate λ and jump size distribution function F , then $D_{\mathcal{G}}$ is the set of all bounded measurable functions on S and

$$(\mathcal{G}f)(x) = \lambda \int_{\mathbb{R}} [f(x+u) - f(x)] dF(u) \quad (24)$$

whereas if X_t is standard Brownian motion,

$$(\mathcal{G}f)(x) = \frac{1}{2} f''(x) \quad (25)$$

for all bounded $f : \mathbb{R} \rightarrow \mathbb{R}$ having a bounded continuous second derivative (in this case it is not obvious what $D_{\mathcal{G}}$ is).

In general, the generator $(\mathcal{G}, D_{\mathcal{G}})$ does not determine the transition probabilities uniquely. However, it leads to Kolmogorov's so-called *backward equations* and *forward equations*, which are valid under smoothness conditions on $p_t(x, B)$. Setting $f_{t, B}(x) = p_t(x, B)$, the backward equations are

$$(\mathcal{G}f_{t, B})(x) = \frac{\partial f_{t, B}}{\partial t}(x) \quad (26)$$

The forward equations are

$$\int (\mathcal{G}f)(u) p_t(x, du) = \int f(u) \frac{\partial}{\partial t} p_t(x, du), \quad f \in D_{\mathcal{G}} \quad (27)$$

Uniqueness can be achieved by restricting the domain of $\mathcal{G}$ to the set $\overline{D}_{\mathcal{G}}$ of all bounded measurable functions on S for which (a) $\lim_{t \rightarrow 0} \mathbb{E}_x(f(X_t)) = f(x)$ for all $x \in S$ and (b) the ratio on the right side of equation (23) converges to $(\mathcal{G}f)(x)$ and is uniformly bounded in x for sufficiently small t . Then if two MPs have the same generator $\mathcal{G}$ with the same restricted domain $\overline{D}_{\mathcal{G}}$, they have the same law.

The strong Markov property does not hold in general for MPs in continuous time. It is valid if the stopping time takes only countably many values. Arbitrary stopping times can be approximated by those with countably many values under regularity conditions on the sample paths, and the strong Markov property can be carried over to more general cases. For example, it holds if X_t is a Feller process and has right-continuous paths. An MP with state space $\mathbb{R}$ is called a *Feller process* if for every continuous function f on the state space satisfying $\lim_{|x| \rightarrow \infty} f(x) = 0$ the function $x \mapsto \mathbb{E}_x(f(X_t))$ has the same properties and $\lim_{t \rightarrow 0} \mathbb{E}_x(f(X_t)) = f(x)$ for all x . For example, Lévy processes, diffusions, and Markov jump processes are Feller processes. Every Feller process has a version that has right-continuous paths with left-hand limits. A very useful property of Feller processes is that for any $f \in D_{\mathcal{G}}$ the process

$$f(X_t) - \int_0^t (\mathcal{G}f)(X_s) ds$$

is a martingale. *Dynkin's formula* states that

$$\mathbb{E}_x(f(X_\tau)) = f(x) + \mathbb{E}_x \left(\int_0^\tau (\mathcal{G}f)(X_s) ds \right) \quad (28)$$

for every stopping time τ for which $\mathbb{E}_x(\tau) < \infty$. In the next section we present a typical example of how these methods can be employed in stochastic modeling.

Example: The Performance of a Replacement Policy

Consider a technical system subject to fatal failure at some random time σ . The state of the system X_t , $t \geq 0$, is described by a real number indicating its extent of attrition. The process $(X_t)_{t \geq 0}$ starts at $X_0 = 0$

and increases linearly at rate $c(J_t)$, where $(J_t)_{t \geq 0}$ is a “modulating” irreducible Markov chain having state space $\{1, \dots, n\}$ and the rates $c(j)$ satisfy $c(1) > c(2) > \dots > c(n) \geq 0$. The failure rate $r(x)$ is assumed to be a function of the state variable x . The system has to run indefinitely; upon failure it has to be replaced by a new identical one. However, it can also be replaced preventively when its attrition reaches a certain threshold $a > 0$ which has to be specified by the controller. Thus, setting $T_a = \inf\{t > 0 \mid X_t = a\}$, the first replacement takes place at time $\min[T_a, \sigma]$. Suppose that after replacement the modulating chain is also restarted at some fixed state i_0 . We want to determine the performance of the replacement strategy T_a as a function of a .

The underlying MP of this system is two dimensional: $Z_t = (X_t, J_t)$. The generator of Z_t is of course defined analogously to the section titled “Continuous-Time Markov Processes” by $(\mathcal{G}f)(x, i) = \lim_{t \rightarrow 0} t^{-1} [\mathbb{E}_{x,i}(f(Z_t)) - f(x, i)]$ for functions $f: \mathbb{R}_+ \times \{1, \dots, n\} \rightarrow \mathbb{R}$. It can be shown that

$$\begin{aligned} (\mathcal{G}f)(x, i) &= c(i)f'(x, i) + \sum_{j \neq i} q_{ij}f(x, j) \\ &\quad - (q_i + r(x))f(x, i) \\ &\quad + r(x) \int_{[0,x)} f(y, i) \mu_x(dy), \\ i &= 1, \dots, n \end{aligned} \quad (29)$$

or in matrix form

$$\begin{aligned} (\mathcal{G}f)(x) &= Cf'(x) + (Q - r(x)E)f(x) \\ &\quad + r(x)D_f(x) \end{aligned} \quad (30)$$

where $f'(x, i)$ denotes the derivative of f with respect to x and

1. $f(x) = (f(x, 1), \dots, f(x, n))^t$;
2. $Q = (q_{ij})_{i,j \in \{1, \dots, n\}}$ is the generator of the Markov chain J_t and $q_i = -q_{ii}$;
3. C and $D_f(x)$ are diagonal matrices with diagonal entries $c(i)$ and $\int_{[0,x)} f(y, i) \mu_x(dy)$, respectively;
4. E is the $n \times n$ identity matrix.

Now assume a replacement of a still functioning system costs C_1 and a replacement upon disaster costs C_2 (where $C_1 < C_2$). Then the long-run average cost

of running the system when using the replacement policy T_a is given by

$$C(a) = \frac{C_1 \mathbb{P}_{(0,i_0)}(\min[T_a, \sigma] = T_a) + C_2(1 - \mathbb{P}_{(0,i_0)}(\min[T_a, \sigma] = T_a))}{\mathbb{E}_{(0,i_0)}(\min[T_a, \sigma])} \quad (31)$$

Hence, we have to compute

$$\mathbb{P}_{(x,i)}(\min[T_a, \sigma] = T_a) \quad \text{and} \quad \mathbb{E}_{(x,i)}(\min[T_a, \sigma]).$$

Once these quantities are known as *functions of a* one can try to minimize $C(a)$.

This problem can be tackled as follows. Suppose the process is killed at time σ by entering into a “coffin state” ∂ . By Dynkin’s formula, we have

$$f(x, i) + \mathbb{E}_{(x,i)}\left(\int_0^T (\mathcal{G}f)(Z_t) dt\right) = \mathbb{E}_{(x,i)}(f(Z_T)) \quad (32)$$

for f bounded and in the domain of $\mathcal{G}$ and T any integrable stopping time. Now apply equation (32) to $T = \min[T_a, \sigma]$ in two cases:

1. $f = f_1$ such that $(\mathcal{G}f_1)(x, i) = 0$, $x \in (0, a)$, and $f_1(\partial) = 0$, $f_1(a, i) = 1$.
2. $f = f_2$ such that $(\mathcal{G}f_2)(x, i) = -1$, $x \in (0, a)$, and $f_2(\partial) = 0$, $f_2(a, i) = 0$.

A moment’s reflection shows that if f_1, f_2 have these properties, then

$$f_1(x, i) = \mathbb{P}_{(x,i)}(\min[T_a, \sigma] = T_a) \quad (33)$$

$$f_2(x, i) = \mathbb{E}_{(x,i)}(\min[T_a, \sigma]) \quad (34)$$

Hence, we have to solve

$$Cf'(x) + (Q - r(x)E)f(x) = (0, \dots, 0)^t \quad (35)$$

subject to

$$f(a, \cdot) = (1, \dots, 1)^t \quad (36)$$

and

$$Cf'(x) + (Q - r(x)E)f(x) = (-1, \dots, -1)^t \quad (37)$$

subject to

$$f(a, \cdot) = (0, \dots, 0)^t \quad (38)$$

These are linear systems of differential equations that can be dealt with using standard methods. For

special failure rate functions $r(x)$ one can even obtain closed-form solutions and thus determine the long-run average cost $C(a)$ explicitly.

Continuous-Time MPs with Countable State Space

Let the state space of X_t be a set of integers. Then the transition probabilities are given by the set of functions $p_{ij}(t) = \mathbb{P}_i(X_t = j)$, $t > 0$, where $i, j \in S$, which have the following properties:

1. $p_{ij}(t) \geq 0$, $\sum_{j \in S} p_{ij}(t) = 1$;
2. $p_{ij}(t + s) = \sum_{k \in S} p_{ik}(t)p_{kj}(s)$;
3. $\lim_{t \rightarrow 0} p_{ij}(t) = \delta_{ij}$.

It follows from 1 to 3 that the limits $\lim_{t \rightarrow 0} t^{-1} p_{ij}(t) = \lambda_{ij}$, $i \neq j$, and $\lim_{t \rightarrow 0} t^{-1} [1 - p_{ii}(t)] = \lambda_i$ exist, but the latter ones may be infinite. If λ_i is finite for some i , the functions $p_{ij}(t)$, $j \in S$, are continuously differentiable on $(0, \infty)$ and we have the linear approximations

$$p_{ij}(t) = \lambda_{ij}t + o(t), \quad j \neq i \quad (39)$$

$$p_{ij}(t) = 1 - \lambda_i t + o(t) \quad (40)$$

as $t \rightarrow 0$. Thus, λ_{ij} can be interpreted as the transition rate from i to j and λ_i as the total transition rate away from i . From now on we assume that $\sum_{j \neq i} \lambda_{ij} = \lambda_i < \infty$ for all states i . Then the backward equations are valid in the form

$$p'_{ij}(t) = -\lambda_i p_{ij}(t) + \sum_{k \neq i} \lambda_{ik} p_{kj}(t) \quad (41)$$

The forward equations are

$$p'_{ij}(t) = -\lambda_j p_{ij}(t) + \sum_{k \neq j} \lambda_{kj} p_{ik}(t) \quad (42)$$

Equation (42) does not hold in general; its derivation additionally requires that

$$\lim_{t \rightarrow 0} \sup_{i \neq j} |t^{-1} p_{ij}(t) - \lambda_{ij}| = 0 \quad (43)$$

a uniformity property that is satisfied in most concrete models. Let Λ be the matrix with entries λ_{ij} , $i \neq j$, and $-\lambda_i$ on the diagonal, and let $P(t)$ and $P'(t)$ be the matrices with entries $p_{ij}(t)$ and $p'_{ij}(t)$, respectively.

8 Markov Processes

Then equation (41) and equation (42) can be written as the linear matrix differential equations

$$P'(t) = P(t)\Lambda \quad (44)$$

$$P'(t) = \Lambda P(t) \quad (45)$$

with the initial condition $P(0) = (\delta_{ij})$. A formal solution to equation (44) and equation (45) is

$$P(t) = e^{\Lambda t} \quad (46)$$

If the state space is finite, equation (46) is the unique solution of equation (41) (and of equation (42)), and when Λ can be diagonalized, $e^{\Lambda t}$ can be expressed in terms of eigenvectors and eigenvalues. The case of an infinite state space is more complicated.

In many stochastic systems transition probabilities for the successively visited states and total transition rates λ_i are given by the intuitive formulation of the model. The standard construction of MPs with countable state space starts from an arbitrary discrete-time MP $(Y_n)_{n \in \mathbb{Z}_+}$, giving the sequence of visited states, and arbitrary non-negative sojourn time parameters λ_i for the holding times (which turn out to be exponential). Let $Q = (q_{ij})_{i,j \in S}$ be a transition matrix satisfying $q_{ii} = 0$ for all i . We introduce an extra point $\partial \notin S$ to account for possible “explosions” of the MP in finite time. Let $S_\partial = S \cup \{\partial\}$ and extend Q to a transition matrix Q_∂ on S_∂ by making ∂ an absorbing state, i.e., setting $q_{\partial,\partial} = 1$. Define the underlying sample space by

$$\Omega = (0, \infty]^{\mathbb{N}} \times (S_\partial)^{\mathbb{N}} \quad (47)$$

and let $T_0, T_1, \dots : \Omega \rightarrow (0, \infty]$ and $Y_0, Y_1, \dots : \Omega \rightarrow S_\partial$ be the coordinate projections. Then one can, for any probability vector $\pi = (\pi_i)_{i \in S}$, construct probability measures $\mathbb{P}_\pi$ on Ω , endowed with its product σ -algebra, such that, under $\mathbb{P}_\pi$:

1. $(Y_n)_{n \in \mathbb{Z}_+}$ is a discrete-time MP on S_∂ governed by Q_∂ and satisfying $\mathbb{P}_\pi(Y_0 = i) = \pi_i$.
2. Conditional on $(Y_n)_{n \in \mathbb{Z}_+}$, the random variables $T_0, T_1, \dots$, are independent and T_n is exponential with rate λ_{Y_n} .

Then

$$X_t = \begin{cases} Y_n, & \text{if } T_0 + \dots + T_{n-1} \leq t < T_0 + \dots + T_n, \\ n \in \mathbb{Z}_+ \\ \partial, & \text{if } t \geq \sup_{n \in \mathbb{Z}_+} (T_0 + \dots + T_n) \end{cases} \quad (48)$$

defines an MP which runs through the states $Y_0, Y_1, \dots$ and has for every visit to state i an exponential sojourn time (with mean λ_i^{-1}) which is independent of its history before and after the current visit. The rates λ_{ij} in equation (39) are given by $\lambda_{ij} = \lambda_i q_{ij}$, $i \neq j$.

This process can be *explosive*, i.e. $\mathbb{P}_i(M < \infty) > 0$ for some i , where $M = \sup_{n \in \mathbb{Z}_+} (T_0 + \dots + T_n)$. According to definition (48), it will stay in ∂ forever after time M , but there is an infinity of other possibilities to define the process after an explosion. The MP constructed by equation (48) is called *minimal* as it minimizes $\mathbb{P}_\pi(X_t = i)$ for all $i \in S$, $t > 0$ and π . Instead of introducing an absorbing extra state, one could define that at every explosion time the process moves to state i with some probability $\alpha_i \geq 0$, where $\sum_{i \in S} \alpha_i = 1$ (in this case one does not need ∂). Formally, starting with M and X_t from the above construction,

$$p_{ij}^{(0)}(t) = \mathbb{P}_i(X_t = j, M > t) \quad (49)$$

is the probability to go from i to j before the first explosion. Now define recursively the probability to go from i to j in time t with exactly n explosions in between by setting

$$p_{ij}^{(n)}(t) = \int_0^t \sum_{k \in S} p_{ik}^{(n-1)}(t-s) \alpha_k \mathbb{P}_k(M \in ds), \quad n \geq 1 \quad (50)$$

and let

$$p_{ij}(t) = \sum_{n=0}^{\infty} p_{ij}^{(n)}(t) \quad (51)$$

It can be shown that these $p_{ij}(t)$ define a family of transition probability functions which satisfy the backward but not the forward equations.

The MP constructed by equation (48) is nonexplosive (that is, $\mathbb{P}_i(M < \infty) = 0$ for every $i \in S$) if and only if the vector equation $\Lambda a = a$, $a = (a_i)_{i \in S}$ admits only the trivial solution $a = 0$. Sufficient conditions to rule out explosions are: (a) $\sup_{i \in S} \lambda_i < \infty$ or (b) Y_n is recurrent.

The asymptotic behavior of X_t is slightly simpler than in the discrete-time case because periodicity phenomena are smoothed out by the exponential sojourn times. In the following we consider a minimal MP X_t and summarize the main results. X_t is called

irreducible if $p_{ij}(t) > 0$ for some $t > 0$ for all $i, j \in S$ (this is equivalent to the irreducibility of Y_n). A state i is called *recurrent (transient)* if it is recurrent (transient) for Y_n , and the MP itself is said to be recurrent (transient) if all states have this property.

1. If X_t is irreducible and recurrent, it possesses a stationary measure $\rho = (\rho_i)_{i \in S}$, i.e., $\rho \neq 0$, $0 \leq \rho_i < \infty$ and $\rho_i = \sum_{j \in S} \rho_j p_{ji}(t)$ for all $i \in S$ and $t > 0$. Such a ρ is unique up to positive factors and is given by $\tilde{\rho}_i = \mu_i / \lambda_i$, where $(\tilde{\rho}_i)_{i \in S}$ is stationary for Y_n .
2. Alternatively, ρ_i can be characterized (up to a constant factor) as the expected time spent in i between two consecutive visits of j , where j is an arbitrary fixed state, or as solution of the equation $\rho \Lambda = 0$.
3. If the stationary measure has finite total mass, the MP is called *ergodic*. If the MP is irreducible and nonexplosive, it is ergodic if and only if there is a stationary probability distribution; for an irreducible MP to be ergodic it is sufficient that there exists a probability vector $\pi = (\pi_i)_{i \in S}$ solving $\pi \Lambda = 0$ and satisfying $\sum_i \pi_i \lambda_i < \infty$. In this case $\lim_{t \rightarrow \infty} p_{ij}(t) = \pi_j$ for all states i and j . If X_t is irreducible and recurrent but not ergodic, the limits are all equal to zero.

Spelled out, the vector equation $\pi \Lambda = 0$ is tantamount to $\pi_j \lambda_j = \sum_{i \neq j} \rho_i \lambda_{ij}$ for all j ; this means that in steady state the outflow rate of any state is equal to its inflow rate.

WOLFGANG STADJE

Renewal Theory

Basic Definitions

A *renewal process* (RP) is a random sequence $0 \leq S_0 < S_1 < S_2 < \dots$, interpreted as the occurrence times of some phenomenon, for which the interarrival times $X_n = S_n - S_{n-1}$, $n \geq 1$, and $X_0 = S_0$ are independent and $X_1, X_2, \dots$ (but not necessarily X_0) have the same cumulative distribution function (cdf) F . It provides a mathematical model for a system that is completely renewed at times $S_0, S_1, \dots$. The system could for example consist of a single item with lifetime distribution F , which is replaced by a new item of the same kind at every failure time. The item functioning at time zero may not be new so that its residual lifetime S_0 could have a different cdf, say G . If $S_0 = 0$ almost surely (i.e., G corresponds to the point mass at zero), the RP is called *pure*; otherwise it is called *delayed*.

An RP can be equivalently described by its corresponding counting process

$$\begin{aligned} N_t &= \#\{n \geq 0 \mid S_n \leq t\} \\ &= \inf\{n \geq 0 \mid S_n > t\}, \quad t \geq 0 \end{aligned} \quad (1)$$

which gives the number of renewals in $[0, t]$. Note that $N_{S_n} = n + 1$ and that N_t and S_n are related by

$$\{N_t \leq n\} = \{S_n > t\} \quad (2)$$

so that for fixed t the distribution of N_t can be expressed in terms of the n -fold convolutions F^{*n} of F with itself and of G . Renewal theory has as its core the study of the process $(N_t)_{t \geq 0}$. As the basic theory of recurrent events, it is a universal mathematical tool of stochastic modeling. Extensive treatments with a wealth of applications can be found in [1–4]. We will focus on the standard framework and not consider extensions and ramifications like **Markov RPs** or nonlinear or multidimensional renewal theory. It can be shown that $\mathbb{E}[\exp\{aN_t\}] < \infty$ for some $\alpha > 0$; this implies that all **moments** of N_t are finite. The main results of renewal theory concern the convolution series

$$U(t) = \sum_{n=0}^{\infty} F^{*n} \quad (3)$$

the so-called renewal function. Here F^{*n} denotes the n -fold convolution of F with itself and $F^{*0} = 1_{[0, \infty)}$. For a pure RP, $U(t)$ is equal to $\mathbb{E}[N_t]$, the expected number of renewals in $[0, t]$.

Explicit formulas for $U(t)$ are available in a few cases; for example if F is uniform [1, 5] Erlang [6], truncated exponential [7], or Weibull [8]; for the phase-type case see [3]. The counting process of a pure RP with $\exp(\lambda)$ -distributed interarrival times is of course nothing but a homogeneous **Poisson process**; in this case $U(t) = 1 + \lambda t$.

The Renewal Equation and the Renewal Theorem

In this section we consider a pure RP. The function $U(t)$ satisfies the equation

$$U(t) = 1 + \int_0^t U(t-x) dF(x), \quad t \geq 0 \quad (4)$$

To see equation (4), condition N_t on the first renewal time S_1 and note that $\mathbb{E}[N_t \mid S_1 = x] = 1$ for $t < x$ and $\mathbb{E}[N_t \mid S_1 = x] = 1 + U(t-x)$ for $t \geq x$.

Equation (4) is a special case of the *renewal equation*

$$Z(t) = z(t) + \int_0^t Z(t-x) dF(x) \quad (5)$$

In equation (5) the function $z(t)$ and the cdf F are given and $Z(t)$ is an unknown function on $[0, \infty)$. If z is bounded on every finite interval, it can be shown that

$$Z(t) = \int_0^t z(t-x) dU(x) \quad (6)$$

is a solution of equation (5), and indeed the only one that is bounded on finite intervals.

The *renewal theorem* describes the asymptotic behavior of $U(t)$ and of the solutions of corresponding renewal equations. Set $\mu = \mathbb{E}[X_1] \in (0, \infty]$. Intuitively, for $\mu < \infty$ one expects $U(t)$ to grow like t/μ because, on an average, there will be a renewal every μ time units, and indeed it is not difficult to show that

$$\lim_{t \rightarrow \infty} t^{-1} U(t) = \mu^{-1} \quad (7)$$

The renewal theorem extends this idea in a very strong sense. One has to distinguish two cases: (a) If F is concentrated on the multiples $\{a, 2a, 3a, \dots\}$

2 Renewal Theory

of some number $a > 0$, it is said to be *lattice*, and the largest a with this property is called its *period*; (b) if no such a exists, F is called *nonlattice*.

Blackwell's renewal theorem states that if F is nonlattice, then for every $s > 0$,

$$U(t + s) - U(t) \longrightarrow \frac{s}{\mu}, \text{ as } t \longrightarrow \infty \quad (8)$$

while if F is lattice with period a , then

$$U(na) - U((n-1)a) \longrightarrow \frac{a}{\mu}, \text{ as } n \longrightarrow \infty \quad (9)$$

If $\mu = 0$, the limits have to be interpreted as zero, so that we also have a result for this case.

The *key renewal theorem* concerns the solutions of equation (5) for a certain class of functions $z : [0, \infty) \rightarrow \mathbb{R}$. It states that for nonlattice F and any directly Riemann integrable (DRI) z ,

$$Z(t) = \int_0^t z(t-x) dU(x) \longrightarrow \frac{1}{\mu} \int_0^\infty z(x) dx, \text{ as } t \longrightarrow \infty \quad (10)$$

Here a nonnegative function z is called *DRI* if its upper and lower Riemann sums over the entire interval $[0, \infty)$ converge properly. Specifically, let

$$\begin{aligned} M_\alpha^{(n)}(z) &= \sup_{n\alpha \leq x < (n+1)\alpha} z(x), \quad m_\alpha^{(n)}(z) \\ &= \inf_{n\alpha \leq x < (n+1)\alpha} z(x) \end{aligned} \quad (11)$$

for $\alpha > 0$ and $n = 0, 1, 2, \dots$. Then $z \geq 0$ is DRI if

$$\lim_{\alpha \rightarrow 0} \alpha \sum_{n=0}^{\infty} (M_\alpha^{(n)}(z) - m_\alpha^{(n)}(z)) = 0 \quad (12)$$

A real-valued function z on $[0, \infty)$ is DRI if its negative and its positive parts are DRI. For z to be DRI, it is necessary that it is bounded and continuous Lebesgue almost everywhere. Sufficient conditions are (a) z is nonincreasing and Lebesgue integrable or (b) z is continuous Lebesgue almost everywhere and $0 \leq z \leq \tilde{z}$ for some function $\tilde{z}$ satisfying (a).

A direct analytical proof of the renewal theorem can e.g., be found in [1, 3]. A Fourier analytical derivation is given in [9, 10]. An innovative probabilistic approach that has also led to new proofs of the renewal theorem and extensions is the coupling method [11, 12].

Refinements and Applications

We now give a survey of classical results linked with the renewal theorem and consider a pure nonlattice RP.

1. The *age process* and the *residual lifetime process* corresponding to an RP are defined by

$$A_t = t - S_{N_t-1}, \quad R_t = S_{N_t} - t, \quad t \geq 0 \quad (13)$$

They give the time elapsed since the last renewal and the waiting time until the next renewal, respectively. A_t and B_t are strong **Markov processes**. The cdf's $\mathbb{P}(A_t \leq x)$ and $\mathbb{P}(B_t \leq x)$ of A_t and B_t , considered as functions of t for fixed x , both satisfy the renewal equation (5) (with $z(t) = 1_{[0,x]}(t)(1 - F(t))$ and $z(t) = F(t+x) - F(t)$, respectively). Applying the key renewal theorem yields that if $\mu < \infty$ they both have the same limiting stationary cdf,

$$\lim_{t \rightarrow \infty} \mathbb{P}(A_t \leq x) = \lim_{t \rightarrow \infty} \mathbb{P}(B_t \leq x) = F_e(x) \quad (14)$$

which is given by

$$F_e(x) = \frac{1}{\mu} \int_0^x (1 - F(u)) du \quad (15)$$

If the second moment $\mathbb{E}(X_1^2)$ is finite, the expected values $\mathbb{E}(A_t)$ and $\mathbb{E}(B_t)$ converge to $\int_0^\infty x dF_e(x) = \mathbb{E}(X_1^2)/2\mu$, and since $N_t = t + B_t$, it follows that in this case

$$\lim_{t \rightarrow \infty} \left(U(t) - \frac{t}{\mu} - \frac{\mathbb{E}(X_1^2)}{2\mu} \right) = 0 \quad (16)$$

2. The *inspected lifetime* L_t , $t \geq 0$, is defined by $L_t = X_{N_t} = A_t + R_t$. It gives the lifetime of the item active at time t . It can be shown that its limiting cdf is $F_0(x) = \int_0^x (u/\mu) dF(u)$. The fact that the cdf of the inter-renewal times containing a fixed time t is different from F is called the *inspection paradox*. The reason is that sampling the inter-renewal times containing a fixed t favors the larger ones. In the limit, the expected inspected lifetime is $\mathbb{E}[X_1^2]/\mu$, which is greater than μ . In fact, F_0 is stochastically larger than F . One can even prove [13] that the backward sequence $X_{N_t}, X_{N_t-1}, X_{N_t-2}, \dots$ of renewal epochs up to $t+0$ is stochastically decreasing, i.e.

$$\begin{aligned} \mathbb{P}(X_{N_t-n} \leq x) &\geq \mathbb{P}(X_{N_t-m} \leq x) \text{ for all } x \geq 0 \\ &\text{and all } n \geq m \geq 0 \end{aligned} \quad (17)$$

where we set $X_k = 0$ for $k < 0$.

3. If F is absolutely continuous with density f , there is a *renewal density* $u(t)$, i.e. $U(t) = \int_0^t u(s) ds$. It is given by $u = \sum_{n=1}^{\infty} f^{*n}$ and satisfies the renewal equation (5) with $z = f$. In view of Blackwell's renewal theorem one expects the corresponding result for the density:

$$\lim_{t \rightarrow \infty} u(t) = \frac{1}{\mu} \quad (18)$$

Conditions on f for equation (18) to hold were given in [1, 14–18]; the simplest are (a) $\lim_{t \rightarrow \infty} f(t) = 0$ and $\int_0^{\infty} f(x)^{1+\delta} dx < \infty$ for some $\delta > 0$ or (b) f is DRI. If f is just bounded, we have [1]

$$\lim_{t \rightarrow \infty} (u(t) - f(t)) = \frac{1}{\mu} \quad (19)$$

which means that the renewal density asymptotically compensates the possible oscillations of f . Equation (19) also holds if f is unbounded but $\int_0^{\infty} f(x)^2 dx < \infty$ and $\int_0^{\infty} f(x)x \log(1+x) dx < \infty$, and if the second moment of F is finite, we even have

$$u(t) - f(t) - \mu^{-1} = O(t^{-1/2}) \quad (20)$$

see [19, 20]. Further estimates for the rate of convergence and exact upper bounds can be found in [19, 21, 22].

4. The convergence results above can be considerably sharpened if a renewal density exists. Actually only a somewhat weaker condition is needed. The cdf F is called *spread out* if $F^{*n} \geq \varepsilon H$ for some $n \in \mathbb{N}$, $\varepsilon > 0$ and some absolutely continuous cdf H . If F has this property, then *Stone's decomposition* holds: the renewal function U can be written as $U(t) = U_1(t) + U_2(t)$, where U_1 and U_2 are non-decreasing, right-continuous functions on $[0, \infty)$, U_1 has a bounded continuous density $u_1 = dU_1/dt$ satisfying $\lim_{t \rightarrow \infty} u_1(t) = 1/\mu$, and U_2 is bounded. It can then be concluded that the key renewal theorem holds for every Lebesgue integrable bounded function z for which $\lim_{t \rightarrow \infty} z(t) = 0$ (so that z need not be DRI). Moreover, A_t and R_t converge to their common limit F_e in total variation (not just in distribution as in equation (14)). One gets exponential rates of convergence for the total variation distances if F is spread out and additionally $\mathbb{E}[e^{\alpha X_1}] < \infty$ for some $\alpha > 0$. In this situation, if z is bounded and of order $O(e^{-\beta t})$ as $t \rightarrow \infty$, the solution of the corresponding renewal equation converges to $\mu^{-1} \int_0^{\infty} z(t) dt$ exponentially fast.

Delayed Renewal Processes

The results of the sections titled “The Renewal Equation and the Renewal Theorem” and “Refinements and Applications” essentially carry over to delayed RPs. The expected number of renewals in $[0, t]$ is given by

$$\mathbb{E}[N_t] = (G * U)(t) \quad (21)$$

If F and G are lattice with period a , then

$$\mathbb{E}[N_{na}] - \mathbb{E}[N_{(n-1)a}] \longrightarrow \frac{a}{\mu}, \text{ as } n \longrightarrow \infty \quad (22)$$

If F is nonlattice,

$$\mathbb{E}[N_{t+s}] - \mathbb{E}[N_t] \longrightarrow \frac{s}{\mu} \text{ for every } s > 0 \quad (23)$$

and for every DRI function z ,

$$\int_0^t z(t-x) d(G * U)(x) \longrightarrow \frac{1}{\mu} \int_0^{\infty} z(x) dx, \quad \text{as } t \longrightarrow \infty \quad (24)$$

By choosing the “right” cdf for the initial renewal instant S_0 one can make the delayed RP become stationary in the sense that the distribution of the shifted process $(N_{t+s} - N_s)_{t \geq 0}$ is independent of $s \geq 0$, i.e., it is equal to that of $(N_t)_{t \geq 0}$. For any $t \geq 0$, after S_{N_t} (the first S_n in $[t, \infty)$) the RP continues with independent and identically distributed (i.i.d.) inter-renewal times. Thus, if the residual lifetime $R_t = S_{N_t} - t$ has the same distribution for every t , the delayed RP is stationary. If $\mu < \infty$, this can be achieved by assigning to $R_0 = S_0$ the limiting distribution of B_t , having cdf F_e (cf. equation (14)). For this reason F_e is called the *equilibrium distribution* of the RP. In this case $\mathbb{E}[N_t] = t/\mu$. In fact there is a nice construction of a stationary RP with interarrival cdf F . Let L and U be independent random variables where L has cdf F_0 and U is uniform on $(0, 1)$. Let L and U be independent of the i.i.d. sequence $X_1, X_2, \dots$. Construct the RP based on X_n and starting with the initial age $A_0 = UL$ and the initial residual waiting time $R_0 = (1 - U)L$. Then this RP and the associated Markov process (A_t, R_t) are stationary.

Normal and Other Approximations

On the basis of equation (2) between S_n and N_t , one can deduct a normal approximation for N_t

(after standardization) from the standard central limit theorem for S_n . If $\sigma^2 = \text{Var}(X_1) < \infty$, one can conclude that

$$\lim_{t \rightarrow \infty} t^{-1} \text{Var}(N_t) = \frac{\sigma^2}{\mu^3} \quad (25)$$

and, setting $N_t^* = (N_t - \mu^{-1}t)/\mu^{-3/2}\sigma t^{1/2}$,

$$\lim_{t \rightarrow \infty} \mathbb{P}(N_t^* \leq x) = \int_{-\infty}^x (2\pi)^{-1/2} e^{-x^2/2} dx, \quad x \in \mathbb{R} \quad (26)$$

Equation (26) can be extended to an invariance principle. For given $t > 0$ define the process $Y = (Y^{(t)}(s))_{s \in [0,1]}$ by $Y^{(t)}(s) = N_{st}^*$. Y takes values in the function space $D[0,1]$ and it can be shown that it converges weakly to **Brownian motion** as $t \rightarrow \infty$. For weak and strong functional limit theorems for RPs, we refer to [23–26]. A related invariance principle for the process $X^{(n)} = (S_{[nt]})_{t \in [0,1]}$, conditioned on $S_n = s$ for fixed $s > 0$, has been proved in [13]. Here we consider the pure case $S_0 = 0$. The conditional distribution of $X^{(n)}$, given $S_n = s$, on $D[0,1]$ converges to the point mass at the linear function x_s , defined by $x_s(t) = st$, if $\lim_{n \rightarrow \infty} n \mathbb{E}[X_1^2] = 0$. This latter condition is for example satisfied if F is strongly unimodal (i.e., it has a log concave density). Thus, under the assumption that the n th renewal takes place at some fixed time s , the n renewal times in $[0, s]$ tend to be uniformly dispersed in this interval as $n \rightarrow \infty$. Technically, let us measure this dispersion by

$$U_n = \sup_{0 \leq t_1 \leq t_2 \leq s} |n^{-1}[N_{t_2} - N_{t_1}] - s^{-1}(t_2 - t_1)| \quad (27)$$

Then $\mathbb{P}(U_n > \varepsilon \mid S_n = s) = 0$ for all $\varepsilon > 0$.

For a certain range of values of t and n , the probability that $N_t = n + 1$ can be approximated in terms of the Laplace–Stieltjes transform $\hat{F}(\alpha) = \int_0^\infty e^{-\alpha t} dF(t)$ of F , using the analytic method of steepest descent. Assume that for $\ell(\alpha) = \ln \hat{F}(\alpha)$ the equation $\ell'(\alpha) = -t/n$ has exactly one real root ζ . Then for the pure RP with renewal epoch cdf F the probability $P(N_t = n + 1)$ can be approximated by

$$\frac{e^{\zeta t} (1 - \hat{F}(\zeta)) (\hat{F}(\zeta))^n}{(2\pi n \ell''(\zeta))^{1/2} \zeta}$$

for those values of t and n for which $n \ell''(\zeta)$ is large. This technique yields good results in various special cases.

Software Reliability Modeling and Analysis

Introduction

It is a well-known fact that modern society depends more and more heavily on software systems, and this trend will certainly continue in the future. In order to improve the reliability of a software product being developed, it is a common practice to have the software tested extensively prior to its release to customers. The testing of the software is a verification process for software reliability improvement, which is featured by the phenomenon of failure observation and the activity of fault removal. Software reliability models are commonly used to monitor the testing process and to measure and predict present and future software reliability.

Since the early 1970s, over 100 software reliability models have been proposed and studied. In this chapter we give a brief overview of software reliability models and their applications. More detailed reviews of software reliability modeling can be found in Xie [1], Lyu [2], Pham [3], and Xie *et al.* [4]. The readers are also encouraged to read some recent research articles for more in-depth ideas on various issues related to software reliability modeling and applications.

Overview of Some Traditional Software Reliability Models

Software reliability models can be classified into different categories according to different classification systems. Xie [1] provided an extensive coverage of most software reliability models that were widely discussed till that time. Recently, research has focused more on the application and minor extension of those models. In this section we adopt the classification system based on model assumptions.

Markov Models

The Jelinski–Moranda model [5] is the first published Markov model, which has profound influences on software reliability modeling thereafter. The main assumptions of this model are

1. The number of initial faults is an unknown but fixed constant.
2. A detected fault is removed immediately and no new faults are introduced.
3. Times between failures are independent, exponentially distributed random quantities.
4. Each remaining software fault contributes the same amount to the software failure intensity.

Denote by N_0 the number of initial faults in the software before the testing starts, then the initial failure intensity is $N_0\phi$, where ϕ is a constant of proportionality denoting the failure intensity contributed by each fault. Denote by $T_i, i = 1, 2, \dots, N_0$, the time between $(i - 1)$ th and i th failures, then T_i s are independent, exponentially distributed random variables with parameter

$$\lambda_i = \phi[N_0 - (i - 1)], i = 1, 2, \dots, N_0 \quad (1)$$

Many modified versions of the Jelinski–Moranda model have been studied in the literature. Schick and Wolverton [6] proposed a model assuming that times between failures are not exponential but follow Rayleigh distribution. Shanthikumar [7] generalized the Jelinski–Moranda model by using general time-dependent transition probability function. Xie [8] developed a general decreasing failure intensity model allowing for the possibility of different fault sizes. Whittaker *et al.* [9] considered a model which allows use of prior testing data to cover the real-world scenario in which the release build is constructed only after a succession of repairs to buggy prerelease builds. Boland and Singh [10] recently considered a birth-process approach to a related software reliability model.

Most software reliability models are based on the assumption of statistical independence among successive software failures. Goseva–Popstojanova and Trivedi [11] developed the software reliability modeling framework which can consider the phenomena of **failure correlation** and studied its effects on the software reliability measures. A recent paper on a related topic is Dai *et al.* [12].

NHPP Models

For this type of models, the software failure process is assumed to follow a **nonhomogeneous Poisson process** (NHPP). Denote by $N(t)$ the number of

2 Software Reliability Modeling and Analysis

observed failures until time t , the main assumptions of this type of models are

1. $N(0) = 0$.
2. $\{N(t), t \geq 0\}$ has independent increments.
3. At time t , $N(t)$ follows a Poisson distribution with parameter $m(t)$, i.e.,

$$P\{N(t) = n\} = \frac{[m(t)]^n}{n!} \exp[-m(t)], \quad n = 0, 1, 2, \dots \quad (2)$$

where $m(t)$ is called the *mean value function* of the NHPP, which describes the expected cumulative number of experienced **failures** in time interval $(0, t]$.

The *failure intensity function*, $\lambda(t)$, is defined as

$$\begin{aligned} \lambda(t) &\equiv \lim_{\Delta t \rightarrow 0^+} \frac{P(N(t + \Delta t) - N(t) > 0)}{\Delta t} \\ &= \frac{dm(t)}{dt}, \quad t \geq 0 \end{aligned} \quad (3)$$

Generally, by using different mean value function of $m(t)$, we get different NHPP models (Figure 1).

The Goel–Okumoto Model. The most representative NHPP model was proposed by Goel and Okumoto [13]. In fact, many other NHPP models are modifications, or generalizations, of this model. The mean value function of the Goel–Okumoto model is

$$m(t) = a[1 - \exp(-bt)], \quad a > 0, b > 0 \quad (4)$$

where a is the expected number of faults to be eventually detected and b is the failure occurrence

rate per fault. The failure intensity function of the Goel–Okumoto model is

$$\lambda(t) = ab \exp(-bt) \quad (5)$$

The Musa–Okumoto Logarithmic Model. Musa and Okumoto [14] developed a logarithmic Poisson execution time model. The mean value function is

$$m(t) = \frac{1}{\varphi} \ln(\lambda_0 \varphi t + 1), \quad \varphi > 0, \lambda_0 > 0 \quad (6)$$

where λ_0 is the initial failure intensity and φ is the failure intensity decay parameter. Since this model allows infinite number of failures observed, it is also called an *infinite failure model*.

The Yamada S-Shaped NHPP Models. Based on experiences, it is sometimes observed that the curve of the cumulative number of faults is S-shaped. Several different S-shaped NHPP models have been proposed in the existing literature. Among them, the most interesting ones are the delayed S-shaped NHPP model [15] and the inflected S-shaped NHPP model [16]. The mean value function of the delayed S-shaped NHPP model is

$$m(t) = a[1 - (1 + bt) \exp(-bt)], \quad a > 0, b > 0 \quad (7)$$

and the mean value function of the infected S-shaped NHPP model is

$$m(t) = \frac{a[1 - \exp(-bt)]}{[1 + c \exp(-bt)]}, \quad a > 0, b > 0, c > 0 \quad (8)$$

The Log-Power Model. An interesting model called *log-power model* was proposed in Xie and Zhao [17]. It has the mean value function

$$m(t) = a \ln^b(1 + t), \quad a > 0, b > 0 \quad (9)$$

This model is a modification of the traditional Duane model [18] for general repairable system. A useful property is that if we take the logarithmic on both sides of the mean value function, we have

$$\ln m(t) = \ln a + b \ln \ln(1 + t) \quad (10)$$

Hence a graphical procedure is established. If we plot the observed cumulative number of failures versus $(t + 1)$, the plot should tend to be on a straight line

Figure 1 An example of failure intensity function $\lambda(t)$ and mean value function $m(t)$ – the Goel–Okumoto Model

on a log–loglog scale. This can be used to easily estimate the model parameters, and more importantly, to validate the model.

Other NHPP Extensions. NHPP is a very favorable alternative in software reliability modeling, which has continuously been receiving a lot of attention. Yamada *et al.* [19] incorporated the concept of test effort into the Goel–Okumoto model for a better description of the failure phenomenon. Later, Xia *et al.* [20] incorporated the concept of a learning factor into the same model. Chatterjee *et al.* [21] presented a **software reliability growth model** which incorporates the joint effect of test effort and learning factor. Gokhale and Trivedi [22] proposed an enhanced NHPP model which incorporates explicitly the time-varying test-coverage function in its analytical formulation. Teng and Pham [23] considered a model for predicting software reliability by including a random environmental factor.

Bayesian Models

For this type of models, Bayesian assumption is made or a Bayesian inference is adopted. The well-known model by Littlewood and Verrall [24] is the first **Bayesian software reliability** model assuming that times between failures are exponentially distributed with a parameter that is treated as a random variable, which is assumed to have a Gamma prior distribution. There are also many papers dealing with Bayesian treatment of the Jelinski–Moranda model, see e.g., Langberg and Singpurwalla [25], Littlewood and Sofer [26] and Csenki [27]. The most important feature of using a Bayesian model is that prior information can be incorporated into **parameter estimation** procedure.

There is also abundant research on the Bayesian inference for NHPP software reliability models. Kuo *et al.* [28] investigated the Bayesian inference for an NHPP with an *S*-shaped mean value function. Cid and Achcar [29] presented Bayesian analysis for NHPP in software reliability models assuming non-monotonic intensity functions. Pham and Pham [30] proposed a Bayesian model, for which times between failures follow Weibull distributions with stochastically decreasing ordering on the hazard functions of successive failure time intervals. Rees *et al.* [31] used Bayesian graphical models to model the uncertainties involved in testing processes.

Software Metrics–Based Quality Models

Most software reliability models make use of the failure time data during the testing. However, because of the limited amount of data available, the prediction is not accurate. Software metrics–based models take a general modeling approach that makes inference based on various measurement from software product and development processes, called *software metrics*. Normally, models of this kind are in a broader context than sole software reliability estimation as software metrics are useful for the study of the whole development process and quality attributes of the resulting software product.

Usually, software metrics are treated as independent variables which are regarded as software quality indicators, and by using different techniques, the values of dependent variables, i.e., fault-proneness of a software module (a binary Boolean value) or the number of faults in a software module can be predicted. These techniques include logistic regression [32], classification and regression trees [33], **artificial neural networks** [34], and so on.

Point and Interval Estimation for Model Parameters

In each software reliability model, there always exist some parameters that have to be estimated based on historical data. Maximum-likelihood estimation (MLE), due to its many good mathematical properties, is a commonly adopted method for parameter estimation [35]. This will be discussed here.

Point Estimation for NHPP Model Parameters

In practice, the **failure data** may arise in two different types, i.e., numbers of failures or failure times. For the first case, denote by n_i the number of failures observed in time interval $(s_{i-1}, s_i]$, where $0 \equiv s_0 < s_1 < \dots < s_k$ and $s_i (i > 0)$ is the prescribed time point in the software testing process, then the likelihood function for an NHPP model with mean value function $m(t)$ is

$$L(n_1, n_2, \dots, n_k) = \prod_{i=1}^k \frac{[m(s_i) - m(s_{i-1})]^{n_i} \exp \{-[m(s_i) - m(s_{i-1})]\}}{n_i!} \quad (11)$$

4 Software Reliability Modeling and Analysis

The parameters in $m(t)$ can be estimated by maximizing the likelihood function given above. Usually, numerical procedures have to be used.

For the second case, denote by $T_i, i = 1, 2, \dots, k$, the observed k failure times in a software testing process, where k is the prescribed number of failures to be observed, then the likelihood function is

$$L(T_1, T_2, \dots, T_k) = \exp[-m(T_k)] \prod_{i=1}^k \lambda(T_i) \quad (12)$$

Similarly, the NHPP model parameters can be estimated by maximizing the likelihood function given above.

A General Approach for Interval Estimation

In order to find asymptotic **confidence intervals** for the k model parameters, the derivation of the *Fisher information matrix* is needed, which is given by

$$I(\theta_1, \dots, \theta_k) \equiv \begin{bmatrix} -E \left[\frac{\partial^2 \ln L}{\partial \theta_1^2} \right] & -E \left[\frac{\partial^2 \ln L}{\partial \theta_2 \partial \theta_1} \right] & \dots & -E \left[\frac{\partial^2 \ln L}{\partial \theta_k \partial \theta_1} \right] \\ -E \left[\frac{\partial^2 \ln L}{\partial \theta_1 \partial \theta_2} \right] & -E \left[\frac{\partial^2 \ln L}{\partial \theta_2^2} \right] & \dots & -E \left[\frac{\partial^2 \ln L}{\partial \theta_k \partial \theta_2} \right] \\ \dots & \dots & \dots & \dots \\ -E \left[\frac{\partial^2 \ln L}{\partial \theta_1 \partial \theta_k} \right] & -E \left[\frac{\partial^2 \ln L}{\partial \theta_2 \partial \theta_k} \right] & \dots & -E \left[\frac{\partial^2 \ln L}{\partial \theta_k^2} \right] \end{bmatrix} \quad (13)$$

In (13), L is given by (11) or (12). From the asymptotic theory of MLE, when n approaches to infinity, $[\hat{\theta}_1, \dots, \hat{\theta}_k]$ converges in distribution to **k -variate normal distribution** with mean $[\theta_1, \dots, \theta_k]$ and **covariance matrix** I^{-1} . That is, the asymptotic covariance matrix of the MLEs is

$$V_e \equiv \begin{bmatrix} \text{Var}(\hat{\theta}_1) & \text{Cov}(\hat{\theta}_1, \hat{\theta}_2) & \dots & \text{Cov}(\hat{\theta}_1, \hat{\theta}_k) \\ \text{Cov}(\hat{\theta}_2, \hat{\theta}_1) & \text{Var}(\hat{\theta}_2) & \dots & \text{Cov}(\hat{\theta}_2, \hat{\theta}_k) \\ \dots & \dots & \dots & \dots \\ \text{Cov}(\hat{\theta}_k, \hat{\theta}_1) & \text{Cov}(\hat{\theta}_k, \hat{\theta}_2) & \dots & \text{Var}(\hat{\theta}_k) \end{bmatrix} \\ = I^{-1} \quad (14)$$

Therefore, the asymptotic $100(1 - \alpha)\%$ confidence interval for $\hat{\theta}_i$ is

$$\left(\hat{\theta}_i - z_{\alpha/2} \sqrt{\text{Var}(\hat{\theta}_i)}, \hat{\theta}_i + z_{\alpha/2} \sqrt{\text{Var}(\hat{\theta}_i)} \right), i = 1, \dots, k \quad (15)$$

where $z_{\alpha/2}$ is the $1 - \alpha/2$ percentile of the standard normal distribution and the quantity $\text{Var}(\hat{\theta}_i)$ can

be obtained from the covariance matrix given by equation (14).

Since the true values of θ_i 's are unknown, the *observed information matrix* is often used

$$\hat{I}(\hat{\theta}_1, \dots, \hat{\theta}_k) \\ \equiv \begin{bmatrix} -\frac{\partial^2 \ln L}{\partial \theta_1^2} & -\frac{\partial^2 \ln L}{\partial \theta_2 \partial \theta_1} & \dots & -\frac{\partial^2 \ln L}{\partial \theta_k \partial \theta_1} \\ -\frac{\partial^2 \ln L}{\partial \theta_1 \partial \theta_2} & -\frac{\partial^2 \ln L}{\partial \theta_2^2} & \dots & -\frac{\partial^2 \ln L}{\partial \theta_k \partial \theta_2} \\ \dots & \dots & \dots & \dots \\ -\frac{\partial^2 \ln L}{\partial \theta_1 \partial \theta_k} & -\frac{\partial^2 \ln L}{\partial \theta_2 \partial \theta_k} & \dots & -\frac{\partial^2 \ln L}{\partial \theta_k^2} \end{bmatrix} \begin{matrix} \theta_1 = \hat{\theta}_1 \\ \dots \dots \dots \\ \theta_k = \hat{\theta}_k \end{matrix} \quad (16)$$

and the confidence interval for $\hat{\theta}_i$ can be calculated.

If $\Phi \equiv g(\theta_1, \dots, \theta_k)$, where $g(\cdot)$ is a continuous function, then as n converges to infinity, $\hat{\Phi}$ converges

in distribution to normal distribution with mean Φ and variance

$$\text{Var}(\hat{\Phi}) = \sum_{i=1}^k \sum_{j=1}^k \frac{\partial g}{\partial \theta_i} \cdot \frac{\partial g}{\partial \theta_j} \cdot v_{ij} \quad (17)$$

where v_{ij} is the element of the i th row and j th column of the matrix in (16). The asymptotic $100(1 - \alpha)\%$ confidence interval for $\hat{\Phi}$ is

$$\left(\hat{\Phi} - z_{\alpha/2} \sqrt{\text{Var}(\hat{\Phi})}, \hat{\Phi} + z_{\alpha/2} \sqrt{\text{Var}(\hat{\Phi})} \right) \quad (18)$$

The above result can be used to obtain the confidence interval for some useful quantities such as failure intensity or reliability.

An Example

Assume that there are two model parameters, a and b , which is quite common in most of software reliability

models, the Fisher information matrix is given by

$$I \equiv \begin{bmatrix} -E \left[\frac{\partial^2 \ln L}{\partial a^2} \right] & -E \left[\frac{\partial^2 \ln L}{\partial a \partial b} \right] \\ -E \left[\frac{\partial^2 \ln L}{\partial a \partial b} \right] & -E \left[\frac{\partial^2 \ln L}{\partial b^2} \right] \end{bmatrix} \quad (19)$$

The asymptotic covariance matrix of the maximum-likelihood (ML) estimators is the inverse of (19):

$$V_e = I^{-1} = \begin{bmatrix} \text{Var}(\hat{a}) & \text{Cov}(\hat{a}, \hat{b}) \\ \text{Cov}(\hat{a}, \hat{b}) & \text{Var}(\hat{b}) \end{bmatrix} \quad (20)$$

For illustrative purposes, we take the data cited in Table 1 in Zhang and Pham [36]. The observed information matrix is

$$\begin{aligned} \hat{I} &\equiv \begin{bmatrix} -\frac{\partial^2 \ln L}{\partial a^2} & -\frac{\partial^2 \ln L}{\partial a \partial b} \\ -\frac{\partial^2 \ln L}{\partial a \partial b} & -\frac{\partial^2 \ln L}{\partial b^2} \end{bmatrix} \begin{matrix} a = \hat{a} \\ b = \hat{b} \end{matrix} \\ &= \begin{bmatrix} 0.0067 & 1.1095 \\ 1.1095 & 4801.2 \end{bmatrix} \end{aligned} \quad (21)$$

We can then obtain the asymptotic variance and covariance of the MLE as follows

$$\begin{aligned} \text{Var}(\hat{a}) &= 154.85, \text{Var}(\hat{b}) = 2.17 \times 10^{-4} \\ \text{Cov}(\hat{a}, \hat{b}) &= -0.0358 \end{aligned} \quad (22)$$

The 95% confidence intervals on parameters a and b are (117.93, 166.71) and (0.0957, 0.1535), respectively.

Optimal Testing-Resource Allocation for Modular Software Systems

In general, a software development process consists of the following four major phases: specification, design, coding and testing. The testing phase is the most costly and time-consuming one. It is thus very much important for the management to spend the limited testing resource efficiently.

Optimal Testing-Resource Allocation Problem

In this section, we directly consider the case of system optimization problem [4]. For the optimal

testing-resource allocation problem, the following assumptions are made:

1. A software system is composed of n independent modules which are developed and tested independently during the unit testing phase.
2. In the unit testing phase, each software module is subject to failures at random times caused by faults remaining in the software module.
3. The failure observation process of software module i is modeled by an NHPP with mean value function $m_i(t)$, or failure intensity function $\lambda_i(t) \equiv dm_i(t)/dt$.

A total amount of testing time T is available for the whole software system that consists of a few modules. It will be allocated to each software module in such a way that the reliability of the system after the unit testing phase will be maximized.

In the following, we study the optimal testing-resource allocation problem in a generic way. Our formulations and solutions are not restricted to any specific software reliability model but are generally applicable to NHPP models.

Optimal Testing-Resource Allocation for Serial Software Systems

If the software system fails whenever there is a failure with any of the modules that the software system is composed of, then it is called a *serial software system*. The structure for such a system is illustrated in Figure 2.

Problem Formulation and Solution. Denote by T_i the testing time allocated to module i . After T_i unit of time of testing, the failure intensity of module i is $\lambda_i(T_i)$. The reliability of module i is

$$R_i(x|T_i) = \exp\{-\lambda_i(T_i)x\}, x \geq 0, i = 1, 2, \dots, n \quad (23)$$

It should be noted that this formulation is based on operational reliability concept and is different from that based on testing reliability concept, which has

Figure 2 Structure of a serial software system

6 Software Reliability Modeling and Analysis

the formulation as follows

$$R_i(x|T_i) = \exp\{-[m_i(T_i + x) - m_i(T_i)]\},$$

$$x \geq 0, i = 1, 2, \dots, n \quad (24)$$

From a customers' point of view, operational reliability is more important and meaningful than testing reliability [37]. Thus the formulation of equation (23) is more appropriate for the optimal testing-resource allocation problem than equation (24).

The reliability of the software system is thus given by

$$R(x|T_1, \dots, T_n) = \prod_{i=1}^n R_i(x|T_i)$$

$$= \exp\left\{-x \sum_{i=1}^n \lambda_i(T_i)\right\} \quad (25)$$

The optimal testing-resource allocation problem is formulated as

$$\text{Maximize } R(x|T_1, \dots, T_n) = \exp\left\{-x \sum_{i=1}^n \lambda_i(T_i)\right\}$$

$$\text{Subject to } \sum_{i=1}^n T_i \leq T$$

$$\text{and } T_i \geq 0, \quad i = 1, 2, \dots, n \quad (26)$$

The formulation above is equivalent to minimizing the sum of failure intensities, i.e.,

$$\text{Minimize } \sum_{i=1}^n \lambda_i(T_i) \quad (27)$$

and this can also be justified by the assumption that any module failure causes system failure. However, it should be noted that this is not the same as the minimization of the total number of experienced failures, which has been commonly used:

$$\text{Minimize } \sum_{i=1}^n [m_i(T_i + x) - m_i(T_i)] \quad (28)$$

In order to derive a general solution to this problem, traditional mathematical methods can be used. The Lagrangian is constructed as

$$L = \sum_{i=1}^n \lambda_i(T_i) + \lambda \left(\sum_{i=1}^n T_i - T \right) \quad (29)$$

The necessary and sufficient conditions for the minimum are

$$\frac{\partial L}{\partial T_i} = \frac{\partial \lambda_i(T_i)}{\partial T_i} + \lambda \geq 0, i = 1, 2, \dots, n \quad (30)$$

under the condition that $T_i \cdot \frac{\partial L}{\partial T_i} = 0, i = 1, 2, \dots, n$; $\lambda (\sum_{i=1}^n T_i - T) = 0$, and $\lambda \geq 0$

The optimal solution $T_1^*, T_2^*, \dots, T_n^*$ can be obtained by solving the above equations numerically.

Example 1 Assume that the software system is composed of 10 modules, and the testing processes follow the Goel–Okumoto model [13]. An optimization algorithm can be used to obtain the solution [38]. In this case, the Lagrangian becomes

$$L = \sum_{i=1}^{10} a_i b_i \exp(-b_i t) + \lambda \left(\sum_{i=1}^n T_i - T \right) \quad (31)$$

and it can be shown that

If $a_k b_k^2 > \lambda \geq a_{k+1} b_{k+1}^2$, then

$$T_i^* = \begin{cases} \frac{1}{b_i} [\ln(a_i b_i^2) - \ln \lambda] & (i = 1, 2, \dots, k) \\ 0 & (i = k + 1, \dots, 10) \end{cases} \quad (32)$$

where λ is

$$\lambda = \exp\left(\frac{\sum_{i=1}^k \frac{1}{b_i} \ln[a_i b_i^2] - T}{\sum_{i=1}^k \frac{1}{b_i}}\right) \quad (33)$$

Suppose that the parameters of the 10 modules have been estimated and summarized in Table 1, and an

Table 1 Estimated parameters and the optimal testing-resource allocation for the example

Module	a_i	b_i (10^{-4})	T_i^*
1	89	4.1823	9198.6

7	59	0.8819	3661.9
8	68	0.7274	1095.8
9	14	1.5309	0
10	37	0.6824	0

Figure 3 The structure of a mix-structured redundant software system

additional 50 000 h of testing time is to be allocated among the modules. By solving the optimization problem, the optimal allocation is obtained and shown as the last column from the right in Table 1.

Under the optimal allocation, after the unit testing phase the reliability of the software system will be:

$$R(x) = \exp(-0.01997x), \quad x \geq 0 \quad (34)$$

Optimal Testing-Resource Allocation for Redundant Software Systems

It is more appropriate to consider the optimal testing-resource allocation problem for series-parallel mix-structured systems. Figure 3 is an illustration of such a software system, which has m redundant modules and $(n-m)$ serial modules.

For a mix-structured redundant software system as shown in Figure 3, the achieved reliability of the system after unit testing phase is as follows:

$$R(x|T_1, \dots, T_m, T_{m+1}, \dots, T_n) = \left(1 - \prod_{i=1}^m [1 - R_i(x|T_i)]\right) \prod_{j=m+1}^n R_j(x|T_j), \quad x \geq 0 \quad (35)$$

where $R_k(x|T_k)$, $k = 1, 2, \dots, n$, is the operational reliability of module k which can be calculated from equation (23). Thus the optimal testing-resource allocation problem is formulated as

$$\begin{aligned} &\text{Maximize } R(x|T_1, \dots, T_m, T_{m+1}, \dots, T_n) \\ &\text{Subject to } \sum_{i=1}^n T_i \leq T, \\ &\text{and } T_i \geq 0, i = 1, 2, \dots, n \end{aligned} \quad (36)$$

Discussions

Software reliability analysis is an important yet tough problem for both computer scientists and statisticians. There are many challenging issues. Many models are based on the modeling of failure data that may not be sufficient for accurate estimation. Other data and information from product and development process could be useful in some cases. However, they are usually not collected systematically or may not be available at all, especially in the early phases in a software development process. Sometimes the increased accuracy with additional information is difficult to be established as well. On the other hand, software reliability prediction is an important issue which has to be done for risk assessment and cost analysis. Therefore, further research and developments are expected.

Availability Models

Introduction

We study a system subject to random deterioration and failure. At failures, repairs or replacements are performed, and the system resumes operation. To characterize the performance of the system, different measures can be used including the ones enumerated below:

1. The probability that the system is functioning at a certain point in time (point availability).
2. The probability that the system is functioning during a specified interval $[u, v]$ (interval availability).
3. The average point availability in a time interval (average availability).
4. The probability distribution of the proportion of time the system is functioning (downtime distribution).
5. The distribution and mean number of system failures during a time interval $[u, v]$.

Traditionally, the focus has been on analyzing the point availability and its limit (the steady-state availability). For a single component, the steady-state formula is given by $MTTF/(MTTF + MTTR)$, where $MTTF$ and $MTTR$ represent the mean time to failure and the mean time to repair (mean repair time), respectively. The steady-state probability of a system comprising several components can then be calculated using the theory of complex (monotone) systems.

Also, performance measures related to a time interval, such as the interval availability, are frequently used. Compared to the steady-state availability, it is of course more complicated to compute the performance measures related to a time interval. Using simplifications and approximations, it is however possible to establish formulae which can be used in practice.

In this article we will look closer at the above availability measures, that is, the first four types of measures in the list above. We establish methods and formulae for computing these measures. We also present some asymptotic results for large time intervals and for systems having highly available components. We first address the one-component case, then more complex systems.

Our focus is on situations where the system is being repaired or replaced immediately at failures. Safety systems where the possible failures are hidden until the system is activated or tested will not be covered. We refer to Rausand and Høyland [1] for a review of availability models applicable in such cases.

Our main reference is Aven and Jensen [2], which also covers analysis of other performance measures apart from the availability measures, including measures related to the number of system failures. Two key references to the classical availability theory are Barlow and Proschan [3, 4].

Basic Setup

Let $X_t = 1$, if the system is functioning at time t , and 0 otherwise. Furthermore let T_k , $k \in \mathbb{N}$ (here $\mathbb{N} = \{1, 2, \dots\}$), represent the length of the k th operation period, and let R_k , $k \in \mathbb{N}$, represent the length of the k th repair/replacement time for the system, see Figure 1. We assume that (T_k) , $k \in \mathbb{N}$, and (R_k) , $k \in \mathbb{N}$, are independent and identically distributed (i.i.d.) sequences of positive random variables. We denote the probability distributions of T_k and R_k by F and G , respectively, and assume that they have finite means μ_F and μ_G , respectively.

In reliability engineering, μ_F and μ_G are referred to as the *mean time to failure* and the *mean time to repair*, respectively.

To simplify the presentation, we also assume that F is an absolutely continuous distribution, that is, F has a density function f and failure rate function λ . We do not make the same assumption for the distribution function G , since that would exclude discrete repair time distributions which are often used in practice.

Figure 1 Time evolution of a failure and repair process for a one-component system starting at time $t = 0$ in the operating state

2 Availability Models

In some cases we also need the variances of F and G , denoted σ_F^2 and σ_G^2 , respectively. In the following, when writing the variance of a random variable, it is tacitly assumed that these are finite.

The sequence $T_1, R_1, T_2, R_2, \dots$ forms an alternating renewal process.

We introduce the following variables

$$S_n = T_1 + \sum_{k=1}^{n-1} (R_k + T_{k+1}), \quad n \in \mathbb{N} \quad (1)$$

and

$$S_n^\circ = \sum_{k=1}^n (T_k + R_k), \quad n \in \mathbb{N} \quad (2)$$

By convention, $S_0 = S_0^\circ = 0$ and sums over empty sets are zero. We see that S_n represents the n th failure time, and S_n° represents the completion time of the n th repair.

The S_n sequence generates a modified (delayed) renewal process N with renewal function M . The first interarrival time has distribution F . All other interarrival times have distribution $F \times G$ (convolution of F and G), with mean $\mu_F + \mu_G$. Let $H^{(n)}$ denote the distribution function of S_n . Then

$$H^{(n)} = F \times (F \times G)^{(n-1)} \quad (3)$$

where B^{*n} denotes the n -fold convolution of a distribution B and as usual B^{*0} equals the distribution with mass of 1 at 0. Note that we have

$$M(t) = \sum_{n=1}^{\infty} H^{(n)}(t) \quad (4)$$

as $N_t = \sum_{n=1}^{\infty} I(S_n \leq t)$, where I is the indicator function. The S_n° sequence generates an ordinary renewal process N° with renewal function M° . The interarrival times, $T_k + R_k$, have distribution $F \times G$, with mean $\mu_F + \mu_G$. Let $H^{\circ(n)}$ denote the distribution function of S_n° . Then

$$H^{\circ(n)} = (F \times G)^{*n} \quad (5)$$

Let α_t denote the forward recurrence time at time t , that is, the time from t to the next event: $\alpha_t = S_{N_t+1} - t$ on $\{X_t = 1\}$, and $\alpha_t = S_{N_t^\circ+1}^\circ - t$ on $\{X_t = 0\}$. Hence, given that the system is up at time t , the forward recurrence time α_t equals the time to the next failure time. If the system is down at time t , the forward recurrence time equals the time to complete the repair. Let F_{α_t} and G_{α_t} denote the conditional

distribution functions of α_t given that $X_t = 1$ and $X_t = 0$, respectively. Then we have for $x \in \mathbb{R}$ (here $\mathbb{R} = (-\infty, \infty)$)

$$\begin{aligned} F_{\alpha_t}(x) &= P(\alpha_t \leq x | X_t = 1) \\ &= P(S_{N_t+1} - t \leq x | X_t = 1) \end{aligned} \quad (6)$$

and

$$\begin{aligned} G_{\alpha_t}(x) &= P(\alpha_t \leq x | X_t = 0) \\ &= P(S_{N_t^\circ+1}^\circ - t \leq x | X_t = 0) \end{aligned} \quad (7)$$

Similarly for the backward recurrence time, we define β_t , F_{β_t} , and G_{β_t} . The backward recurrence time β_t equals the age of the system if the system is up at time t , and the duration of the repair if the system is down at time t , that is, $\beta_t = t - S_{N_t}^\circ$ on $\{X_t = 1\}$, and $\beta_t = t - S_{N_t}$ on $\{X_t = 0\}$.

Point Availability

The point availability $A(t)$, defined by $A(t) = P(X_t = 1)$, is given by

$$\begin{aligned} A(t) &= \bar{F}(t) + \int_0^t \bar{F}(t-x) dM^\circ(x) \\ &= \bar{F}(t) + \bar{F} \times M^\circ(t) \end{aligned} \quad (8)$$

where $\bar{F} = 1 - F$. This follows by using a standard renewal argument. Conditioning on the duration of $T_1 + R_1$, it is not difficult to see that $A(t)$ satisfies the following equation

$$A(t) = \bar{F}(t) + \int_0^t A(t-x) d(F \times G)(x) \quad (9)$$

Hence by the renewal equation (see, e.g., Aven and Jensen [2, p. 245]), Formula (8) is obtained. Alternatively, we may use a more direct approach, writing

$$X_t = I(T_1 > t) + \sum_{n=1}^{\infty} I(S_n^\circ \leq t, S_n^\circ + T_{n+1} > t) \quad (10)$$

which gives equation (8) by taking expectations. The point unavailability $\bar{A}(t)$ is given by $\bar{A}(t) = 1 - A(t) = F(t) - \bar{F} \times M^\circ(t)$.

Calculating the availability at a given point in time t , $A(t)$ is difficult except for a few special cases.

If, for example, the lifetime and repair times are independent and they have exponential distributions, it can be shown using Markov theory (see, e.g., Rausand and Høyland [1]) that the availability of the system at time t equals

$$\frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)t} \quad (11)$$

where λ is the failure rate and μ is the repair rate of the unit. It is assumed that the unit is functioning at time zero.

By the key renewal theorem (see, e.g., Aven and Jensen [2, p. 247]), it follows that

$$\lim_{t \rightarrow \infty} A(t) = \frac{\mu_F}{\mu_F + \mu_G} \quad (12)$$

The right-hand side of equation (12) is called the *limiting availability* (or steady-state availability) and is, for short, denoted by A . The *limiting unavailability* is defined as $\bar{A} = 1 - A$. Usually μ_G is small compared to μ_F , so that

$$\bar{A} \approx \frac{\mu_G}{\mu_F} \quad (13)$$

If the system has an exponential lifetime distribution with failure rate λ , it can be shown that

$$\bar{A}(t) \leq \lambda \int_0^t \bar{G}(s) ds \leq \lambda \mu_G \quad (14)$$

See Aven and Jensen [2, p. 107].

Interval Availability

The interval availability $A[u, v]$ is defined by $A[u, v] = P(X_t = 1, \forall t \in [u, v])$. Using $A[u, v] = A(u)P(\alpha_u > v - u | X_u = 1)$, we see that

$$A[u, v] = \bar{F}_{\alpha_u}(v - u)A(u) \quad (15)$$

The interval availability for the interval $[t, t + w]$, that is, the probability that the system is up at time t and the forward recurrence time at time t is greater than w is given by

$$\begin{aligned} A[t, t + w] &= P(X_t = 1, \alpha_t > w) \\ &= \bar{F}(t + w) \\ &\quad + \int_0^t \bar{F}(t - x + w) dM^\circ(x) \end{aligned} \quad (16)$$

This is shown by noting that

$$X_t I(\alpha_t > w) = \sum_{n=0}^{\infty} I(S_n^\circ \leq t, S_n^\circ + T_{n+1} > t + w) \quad (17)$$

By applying the key renewal theorem (see, e.g., Aven and Jensen [2, p. 247]), it follows that

$$\lim_{t \rightarrow \infty} A[t, t + w] = \frac{\int_0^\infty \bar{F}(x) dx}{\mu_F + \mu_G} \quad (18)$$

The limit $\int_0^\infty \bar{F}(x) dx / (\mu_F + \mu_G)$ is the asymptotic distribution of the forward recurrence time α_t and is denoted by $F_\infty(w)$. Similarly, we define the asymptotic distribution $G_\infty(w)$ of the backward recurrence time β_t .

Downtime Distribution

Let Y_u represent the downtime in the interval $[0, u]$. Then the expected downtime in $[0, u]$ is given by

$$EY_u = \int_0^u \bar{A}(t) dt \quad (19)$$

This result follows by observing that

$$\begin{aligned} EY_u &= E \int_0^u (1 - X_t) dt \\ &= \int_0^u E(1 - X_t) dt \\ &= \int_0^u \bar{A}(t) dt \end{aligned} \quad (20)$$

Using equation (19), we see that, asymptotically, the (expected) proportion of time the system is down equals the limiting unavailability, that is,

$$\lim_{u \rightarrow \infty} \frac{EY_u}{u} = \bar{A} \quad (21)$$

Furthermore, with probability one,

$$\lim_{u \rightarrow \infty} \frac{Y_u}{u} = \bar{A} \quad (22)$$

The renewal reward theorem (see, e.g., Aven and Jensen [2, p. 250]) is used to prove equation (22).

The following results can be shown for the distribution of the downtime (see Aven and Jensen [2, pp. 109–111]):

4 Availability Models

Theorem 1 *The distribution of the downtime in a time interval $[0, u]$ is given by*

$$P(Y_u \leq y) = \sum_{n=0}^{\infty} G^{*n}(y) [F^{*n}(u - y) - F^{*(n+1)}(u - y)] \quad (23)$$

Different versions of this result have been formulated and proved in the literature, for example [5, 6]. The first version was established by Takács. Theorem 1 is from Haukås and Aven [7].

In the case that the interval is rather long, the downtime will be approximately normally distributed, as is shown in Theorem 2.

Theorem 2 *The asymptotic distribution of Y_u as $u \rightarrow \infty$, is given by*

$$\sqrt{u} \left(\frac{Y_u}{u} - \bar{A} \right) \xrightarrow{D} N(0, \tau^2) \quad (24)$$

where

$$\tau^2 = \frac{\mu_F^2 \sigma_G^2 + \mu_G^2 \sigma_F^2}{(\mu_F + \mu_G)^3} \quad (25)$$

Here $\xrightarrow{D}$ means convergence in distribution and $N(0, \tau^2)$ refers to a normally distributed random variable with mean zero and variance τ^2 . The theorem follows by applying the central limit theorem for **renewal processes**, see Aven and Jensen [2, p. 150].

Steady-State Distribution

The asymptotic results established above provide good approximations for the performance measures related to a given point in time or an interval. Based on the asymptotic values, we can define a stationary (steady-state) process having these asymptotic values as their distributions and means. To define such a process in our case, we generalize the model analyzed above by allowing X_0 to be 0 or 1. Thus the time evolution of the process is as shown in Figure 1 beginning with an uptime, or similarly starting with a downtime. The process is characterized by the parameters $A(0)$, $F^*(t)$, $F(t)$, $G^*(t)$, $G(t)$, where $F^*(t)$ denotes the distribution of the first uptime provided that the system starts in state 1 at time 0 (i.e., $X_0 = 1$) and $G^*(t)$ denotes the distribution of the first downtime provided that the system starts

in state 0 at time 0 (i.e., $X_0 = 0$). Now assuming that $F^*(t)$ and $G^*(t)$ are equal to the asymptotic distributions of the recurrence times, that is, $F_\infty(t)$ and $G_\infty(t)$, respectively, and $A(0) = A$, then it can be shown that the process (X_t, α_t) is stationary, see Birolini [5]. This means that we have, for example,

$$A(t) = A, \quad \forall t \in \mathbb{R}_+ \quad (26)$$

$$A[u, u + w] = \frac{\int_w^\infty \bar{F}(x) dx}{\mu_F + \mu_G}, \quad \forall u, w \in \mathbb{R}_+ = [0, \infty] \quad (27)$$

Monotone Systems

Consider now a binary monotone system comprising n independent components. For each component, we define a model as in the section titled “Basic Setup”, indexed by “ i ”. The uptimes and downtimes of component i are thus denoted by T_{ik} and R_{ik} , with distributions F_i and G_i , respectively. The lifetime distribution F_i is absolutely continuous with a failure rate function $\lambda_i(t)$. Let $\Phi : \{0, 1\}^n \rightarrow \{0, 1\}$ be the structure function of the system, which is assumed to be monotone, that is, the structure function Φ is nondecreasing in each argument, and $\Phi(\mathbf{0}) = 0$ and $\Phi(\mathbf{1}) = 1$. The possible states of the system, “functioning” and “not functioning”, are indicated by “1” and “0”, respectively, as for the components. Then $\Phi_t = \Phi(\mathbf{X}_t)$ describes the state of the system at time t , where $\mathbf{X}_t = (X_t(1), \dots, X_t(n))$.

Let p_i denote the reliability of component i , that is, $p_i = P(X_i = 1)$. Then if the components (i.e., the X_i ’s) are independent, the reliability of the system, $P(\Phi = 1)$, is a function of the p_i ’s. This function is referred to as the *reliability function* and is denoted by $h(\mathbf{p})$, where $\mathbf{p} = (p_1, p_2, \dots, p_n)$.

Point Availability

The following results show that the point availability (limiting availability) of a monotone system is equal to the reliability function h with the component reliabilities replaced by the component availabilities $A_i(t)$ (A_i).

Theorem 3 The system availability at time t , $A(t)$, and the limiting system availability, $\lim_{t \rightarrow \infty} A(t)$, are given by

$$A(t) = h(A_1(t), A_2(t), \dots, A_n(t)) = h(\mathbf{A}(t)) \quad (28)$$

$$\lim_{t \rightarrow \infty} A(t) = h(A_1, A_2, \dots, A_n) = h(\mathbf{A}) \quad (29)$$

Equation (28) is simply an application of the reliability function formula with $A_i(t) = P(X_t(i) = 1)$. Since the reliability function $h(\mathbf{p})$ is a linear function in each p_i , and therefore a continuous function, it follows that $A(t) \rightarrow h(A_1, A_2, \dots, A_n)$ as $t \rightarrow \infty$, which proves equation (29).

The limiting system availability can also be interpreted as the expected proportion of time the system is operating in the long run, or as the long-run average availability, noting that

$$\begin{aligned} \lim_{t \rightarrow \infty} E \left[\frac{1}{t} \int_0^t \Phi_s \, ds \right] &= \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t A(s) \, ds \\ &= \lim_{t \rightarrow \infty} A(t) \end{aligned} \quad (30)$$

Interval Availability

In general, it is difficult to calculate the interval availability for a monotone system. Only in some special cases, it is possible to obtain practical computation formulae, and in the following we take a closer look at some of these.

If the repair times are small compared to the lifetimes, and the lifetimes are exponentially distributed with parameter λ_i , then clearly the number of failures of component i in the time interval $(u, u + w]$, $N_{u+w}(i) - N_u(i)$, is approximately Poisson distributed with parameter $\lambda_i w$. Hence the interval availability $A[0, u]$, which is equal to $P(N_u = 0)$, is approximately exponentially distributed.

If the system is a series system, and we make the same assumptions as above, it is also clear that the number of system failures in the interval $(u, u + w]$ is approximately Poisson distributed with parameter $\sum_{i=1}^n \lambda_i w$. The number of system failures in $[0, t]$, N_t , is approximately a **Poisson process** with intensity $\sum_{i=1}^n \lambda_i$.

If the system is highly available and the components have constant failure rates, the Poisson distribution will in fact produce good approximations also for

more general systems. To motivate this, we observe that the expected number of system failures per unit of time during the interval $(u, u + w]$, $EN_{(u, u+w]}/w$ is approximately equal to the asymptotic system failure rate λ_Φ , and $N_{(u, u+w]}$ is “nearly independent” of the history of N up to u , noting that the process $\mathbf{X}$ frequently restarts itself probabilistically (i.e., $\mathbf{X}$ reenters the state $(1, 1, \dots, 1)$). The system failure rate λ_Φ is given by

$$\lambda_\Phi = \lim_{u \rightarrow \infty} \frac{EN_u}{u} = \sum_{i=1}^n \frac{h(1_i, \mathbf{A}) - h(0_i, \mathbf{A})}{\mu_{F_i} + \mu_{G_i}} \quad (31)$$

where $h(x_i, \cdot)$ equals the reliability of the system given that the state of component i is x_i . For a proof of the second equality of equation (31), see Aven and Jensen [2, p. 114].

The detailed formulation and proof of the asymptotic result for the interval availability converting to an exponential distribution is lengthy and will not be stated here. We refer to Aven and Jensen [2, p. 119].

Downtime Distribution

In this section we study the distribution of the **system downtime** in a time interval. We immediately observe that the asymptotic expression for the expected average downtime for the one-component case also holds for monotone systems, with $A = h(\mathbf{A})$. Equation (22) requires that the process $\mathbf{X}$ is a regenerative process with finite expected cycle length.

Assume now that the components have constant failure rate and that the components are highly available, that is, the products $\lambda_i \mu_{G_i}$ are small. Then it can be heuristically argued that (Y_u) is approximately a compound Poisson process CP_u ,

$$Y_u \approx \sum_{i=1}^{N_u} Y_i \approx CP_u \quad (32)$$

Here N_u is the number of system failures in $[0, u]$ and Y_i is the downtime of the i th system failure. The dependency between N_u and the random variables Y_i is not “very strong” since N_u is mainly governed by the renewal cycles without system failures. We can ignore downtimes Y_i being the second, third, and so on system failure in a renewal cycle of the process $\mathbf{X}$. The probability of having two or more system failures in a cycle is small since we are assuming highly

available components. This means that the random variables Y_i are approximately i.i.d.

From this we can find an approximate expression for the distribution of Y_u .

A closely related approximation can be established by considering system operational time, as described in the following.

Let N_s^{op} be the number of system failures in $[0, s]$ when we consider operational time. Then, N_s^{op} is approximately a homogeneous Poisson process with intensity λ'_Φ , where λ'_Φ is given by

$$\lambda'_\Phi = \sum_{i=1}^n \frac{h(1_i, \mathbf{A}) - h(0_i, \mathbf{A})}{(\mu_{F_i} + \mu_{G_i})h(\mathbf{A})} \quad (33)$$

To motivate this result, we note that the expected number of system failures per unit of time when considering calendar time is approximately equal to the asymptotic (steady-state) system failure rate λ_Φ , given by (cf. equation (31)),

$$\lambda_\Phi = \sum_{i=1}^n \frac{h(1_i, \mathbf{A}) - h(0_i, \mathbf{A})}{\mu_{F_i} + \mu_{G_i}} \quad (34)$$

Then observing that the ratio between calendar time and operational time is approximately $1/h(\mathbf{A})$, we see that the expected number of system failures per unit of time when considering operational time, $EN^{op}(u, u+w)/w$, is approximately equal to $\lambda_\Phi/h(\mathbf{A})$.

Furthermore, $N_{[u, u+w]}^{op}$ is “nearly independent” of the history of N^{op} up to u , noting that the state process $\mathbf{X}$ frequently restarts itself probabilistically (i.e., $\mathbf{X}$ reenters the state $(1, 1, \dots, 1)$). It can be shown by the argument as for N that $N_{t/\alpha}^{op}$ has an asymptotic Poisson distribution with parameter t . The system downtimes, given system failure, are approximately identically distributed with distribution function $G_\Phi(y)$, say, independent of N^{op} , and approximately independent observing that the state process $\mathbf{X}$ with a high probability restarts itself quickly after a system failure. The distribution function $G_\Phi(y)$ is normally taken as the asymptotic (steady-state) downtime distribution, given system failure, or an approximation to this distribution. For a

parallel system of n identical components, the asymptotic (steady-state) downtime distribution, given system failure, equals

$$G_\Phi(y) = 1 - \bar{G}(y) \left[\frac{\int_y^\infty \bar{G}(x) dx}{\mu_G} \right]^{n-1} \quad (35)$$

We refer to Aven and Jensen [2, Section 4.5], for a proof of this and for derivation of distributions in the general case.

Considering the system as a one-unit system, we can now apply the exact equation (23) for the downtime distribution with the Poisson parameter λ'_Φ . It follows that

$$P(Y_u \leq y) \approx \sum_{n=0}^{\infty} G_\Phi^{*n}(y) \frac{[\lambda'_\Phi(u-y)]^n}{n!} e^{-\lambda'_\Phi(u-y)} \quad (36)$$

Equation (36) gives good approximations for “typical real life cases” with small component availabilities, see [7].

Finally, in this section, a remark on the convergence to the **normal distribution**. The theorem below is “a time average result” – it is not required that the system is highly available. The result generalizes equation (24).

Theorem 4 *If $\mathbf{X}$ is a regenerative process with cycle length S and associated downtime $Y = Y_S$, $\text{Var}[S] < \infty$ and $\text{Var}[Y] < \infty$, then as $t \rightarrow \infty$,*

$$\sqrt{t} \left[\frac{Y_t}{t} - \bar{A} \right] \xrightarrow{D} N(0, \tau_\Phi^2) \quad (37)$$

where

$$\tau_\Phi^2 = \frac{\text{Var}(Y - \bar{A}S)}{ES} \quad (38)$$

$$\bar{A} = \frac{EY}{ES} \quad (39)$$

The result follows by applying the central limit theorem for renewal reward processes.

Final Remarks

This article covers only a small number of availability models compared to the large number of models

presented in the literature, see the survey paper by Smith *et al.* [8]. Our focus has been the basic models. Examples of models not covered are models to incorporate **preventive maintenance** and standby systems. The former category of models is often developed with the purpose of optimizing maintenance (replacement) policies. We refer to Aven and Jensen [2, Chapter 5] and its Bibliographic Notes. See also Dijkhuizen and Heijden [9]. For the latter category of models, we refer to Aven and Jensen [2, Section 4.7.3]. See also the recent papers by Zhang *et al.* [10] and Montoro-Cazorla and Pérez-Ocón [11], and the references therein.

Furthermore, we have not included models where some components remain in “suspended animation” while a component is being repaired/replaced. When repair of the failed component is completed, the remaining components resume operation. At any instant, they are not “as good as new”, but rather as good as they were when the system stopped operating. Then it can be shown that the long-run (expected) proportion of time the system is functioning equals

$$\frac{1}{1 + \sum_{i=1}^n \frac{MTTR_i}{MTTF_i}} \quad (40)$$

see Barlow and Proschan [4] and Aven [12]. This expression is to be compared to

$$h(\mathbf{A}) = \prod_{i=1}^n \frac{MTTF_i}{MTTF_i + MTTR_i} \quad (41)$$

If the component availabilities are high, then

$$h(\mathbf{A}) \approx 1 - \sum_{i=1}^n \bar{A}_i \quad (42)$$

which is seen to be approximately equal to (40).

Markov models have been mentioned above – such models are often used for availability analysis. An additional book reference covering a number of Markov models for availability analysis is Misra [13]. Markov models are used to describe and analyze the movement of the system among various states, from the perfect functioning state to the complete failure state. Markov models are particularly suitable for analyzing smaller systems with complicated **maintenance policies** and possible dependencies between components. On the other

hand, the computational problems can be significant and the assumption of exponential distributions may seem to restrict applicability. However, the so-called phase-type approach can open for other distributions. The phase-type approach makes use of the fact that a distribution function can be approximated by a mixture of Erlang distributions (with the same scale parameter), for example, Asmussen [14] and Tijms [15].

Markov models are a type of multistate systems, and many of the availability results obtained for the binary case have been extended to such systems, see Aven and Jensen [2, Section 4.7.1]. See also the recent paper by Zio *et al.* [16] and the references therein. Finally, we would like to draw attention to semi-Markov models for availability analysis of multistate systems. We refer to Csenki [17] and Limnios [18].

Stochastic Deterioration

Introduction

In order to ensure that an object (system or structure or one of its components) performs its required functions (including safety), maintenance should be performed on a regular basis. To optimize maintenance (*see* **Maintenance Optimization**), information about the time to failure and/or the deteriorating condition is needed. Unfortunately, there is a lot of uncertainty involved in the deterioration of an object. Mathematical models can be used to account for the stochastic nature of deterioration over time. For this purpose, we distinguish two approaches in modeling deterioration [1, Chapter 1]: the actuarial approach based on the notion of failure rate and the physical approach based on the notion of failure due to the stress exceeding the strength (*see* **Stress–Strength Model**).

Failure Rate Function

A lifetime distribution represents the uncertainty in the time to failure of an object. Let the lifetime have a cumulative probability distribution $F(t)$ with **probability density function** $f(t)$, then the failure rate (or hazard rate) function is defined as

$$r(t) = \frac{f(t)}{1 - F(t)} = \frac{f(t)}{\bar{F}(t)}, \quad t > 0 \quad (1)$$

(Barlow and Proschan [2, Chapter 2]). A probabilistic interpretation of the failure rate function is that $r(t) dt$ represents the probability that an object of age t will fail in the time interval $[t, t + dt]$. For deteriorating objects, the failure rate is increasing. By integrating both sides of equation (1) and then exponentiating, we obtain the survival function

$$\bar{F}(t) = \exp \left\{ - \int_0^t r(\tau) d\tau \right\} \quad (2)$$

Lifetime distributions and failure rate functions are especially useful in mechanical and electrical engineering. In these fields, one often considers equipment which can assume at most two states: the functioning state and the failed state. A structure, on the other hand, can be in a range of states depending on its degrading condition. A disadvantage of failure

rates is that they cannot be observed or measured for a particular object [3].

Time-Dependent Stress–Strength Model

The physical approach to deterioration modeling identifies an object's resistance R (or strength), on the one hand, and its applied stress S (or load), on the other hand. Failure is defined as the event at which the stress is greater than the resistance; that is, $S > R$. Assuming both the resistance and the strength to be a random quantity, the reliability is defined as the probability $\Pr\{R > S\}$. In a physics-based deterioration model, it is recommended to model deterioration in terms of a time-dependent stochastic process $\{X(t), t \geq 0\}$, where $X(t)$ is a random quantity for all $t \geq 0$. A resistance subject to deterioration is then defined as $R(t) = r_0 - X(t)$, where r_0 is the initial resistance. For modeling stochastic deterioration, we can use stochastic processes such as a random deterioration-rate model or a **Markov process**.

Random Deterioration-Rate Model

In structural reliability, time-dependent **degradation** functions are advocated for which the coefficients (such as the average deterioration rate) are random quantities [4, 5]. These stochastic processes are also called *degradation-path models*. An example of such a model is the cumulative amount of deterioration at time t being defined as $X(t) = At$ for all $t \geq 0$, where the average deterioration rate A has a probability distribution. However, according to Pandey *et al.* [6], the sample paths of such models are straight lines and a single inspection thus fixes the future deterioration beforehand. Although the random deterioration-rate model might be used as an approximation, one should be careful as soon as inspections are involved. For the purpose of inspection and maintenance modeling, we therefore have to rely on other stochastic processes (such as Markov processes), which properly capture the temporal variability associated with the evolution of deterioration.

Markov Process

Deterioration is usually assumed to be a Markov process [2, Chapter 5] (*see* **Markov Processes**). Roughly speaking, a Markov process is a stochastic process

2 Stochastic Deterioration

with the property that, given the value of $X(t)$, the values of $X(\tau)$, where $\tau > t$, are independent of the values of $X(u)$, $u < t$. That is, the conditional distribution of the future $X(\tau)$, given the present $X(t)$ and the past $X(u)$, $u < t$, is independent of the past. Classes of Markov processes which are useful for modeling stochastic deterioration are discrete-time Markov processes having a finite or countable state space (called *Markov chains*) and continuous-time Markov processes with independent increments such as the **Brownian motion** with drift, the compound **Poisson process**, the Lévy process, and the gamma process. The assumption of independent increments is more restrictive than the Markov property. Because the increment $X(\tau) - X(t)$ is independent of $X(t)$ and $X(\tau) = X(t) + [X(\tau) - X(t)]$, the stochastic process $\{X(t), t \geq 0\}$ is Markovian. Hence, damage accumulation with independent increments naturally leads to the Markov property.

Finite-State Markov Process. Assume that there is a finite or countable state space. This means that the condition of an object can be in any one of $n > 0$ discrete states or categories. A Markov chain is a discrete-time stochastic process $\{X_t, t = 0, 1, 2, \dots\}$ for which the Markovian property holds. To define the Markov chain X_t , it is necessary to assess the transition probabilities between all possible condition state pairs. If there are n states, then this results in an $n \times n$ -matrix $P = \|p_{ij}\|$, where the probability of a transition between states i and j during one unit of time is denoted by $p_{ij} = \Pr\{X_{t+1} = j | X_t = i\}$. If this transition probability does not depend on t (i.e., does not depend on how long the process has been running), then the process is called *stationary* in time. Obviously, the probability of moving from one state to any other state (including itself) should be 1, or $\sum_{j=1}^n p_{ij} = 1$ for $i, j = 1, \dots, n$. The probability p_{ij}^m of moving from the current state i to state j in m time steps is $p_{ij}^m = \Pr\{X_{t+m} = j | X_t = i\}$. It can be shown [7, Chapter 4] that the m -step transition matrix for a stationary Markov chain can be calculated by multiplying the transition probability matrix m times with itself, P^m .

A semi-Markov process is an extension of a Markov chain in which a random time is added between transitions. Let J_0 be the state of the process $\{X(t), t \geq 0\}$ at the beginning of the process and $J_n, n = 1, 2, \dots$ the state of $X(t)$ after n transitions. The probability of the process moving into state j

in an amount of time less than or equal to t , given that it just moved into state i , is defined as $Q_{ij}(t) = \Pr\{T \leq t, J_{n+1} = j | J_n = i\}$. This probability can be written as the product

$$Q_{ij}(t) = F_{ij}(t)p_{ij} \quad (3)$$

where $p_{ij} = \Pr\{J_{n+1} = j | J_n = i\}$ is the transition probability function of the embedded Markov chain $\{J_n, n = 0, 1, 2, \dots\}$ and $F_{ij}(t) = \Pr\{T \leq t | J_{n+1} = j, J_n = i\}$ represents the conditional probability of the random waiting time T , given that the process moves into state j after previously having moved into state i . Equation (3) shows that transitions in a semi-Markov process have two stages: if the process just moved into state i , it first selects the next state j according to p_{ij} and then waits a random time T according to $F_{ij}(t)$. The semi-Markov process $\{X(t), t \geq 0\}$ may be defined as $X(t) = J_{N(t)}$, where $N(t)$ is the total number of transitions during the interval $(0, t]$. For deterioration modeling, the waiting time distribution is often chosen to have an increasing failure rate to model the increasing probability of the occurrence of a transition the longer an object is in a state. In the case where the waiting times have an exponential distribution, which is a memoryless distribution, the semi-Markov processes are Markovian everywhere. This particular type of processes is referred to as *continuous-time Markov processes* and they are widely used due to their analytical tractability.

Finite-state Markov processes are particularly well suited for modeling the uncertain rate at which objects pass through a finite number of states, categories, or phases (see **Maintenance and Markov Decision Models**). These categories typically range from “very good” to “very bad”, or from “no damage” to “structural failure”, and are often used when the condition of an object can only be assessed by means of visual inspections. If a Markov process is to be used for deterioration modeling, the states or phases should be progressive (i.e., the probability of an improvement is zero) and in many practical applications, it is also assumed that transitions are sequential (i.e., they always proceed from one state to the next in the sequence). This resembles the physical process of deterioration more closely, where objects pass through each successive state before failing.

The parameters of the model, i.e., the transition probabilities or intensities, should be estimated based on expert judgment or based on the available data.

The method of **estimation** depends on the level of detail in the observations of the process. The most information is obtained when the process is continuously monitored, such that each transition in the sequence is observed. For a Markov chain, the maximum-likelihood estimator for each transition probability is then simply $\hat{p}_{ij} = w_{ij}(\sum_{j=1}^n w_{ij})^{-1}$, where w_{ij} is the observed number of transitions from state i to j [8]. The same estimator can be used for the embedded Markov chain in a semi-Markov process and the observed times between transitions allow for fitting the waiting time distributions using classical estimation techniques. This type of detailed information also allows for a Bayesian approach to the estimation of transition probabilities in a Markov chain, see e.g., [9, Chapter 2].

In many practical applications, the process cannot be monitored continuously. If an object is inspected periodically, the type of information that is available is often referred to as *panel data*. Typically, the time between inspections of different objects varies and some objects may be inspected more often than others. Semi-Markov processes are already quite difficult to fit to this type of data, but it becomes more straightforward if deterioration is modeled by a continuous-time Markov process. For this case, the likelihood of w observations $\mathbf{x} = (x_1, \dots, x_w)'$ is $L(\mathbf{x}|\boldsymbol{\theta}) = \prod_{k=1}^w f(x_k|\boldsymbol{\theta})$. The likelihood can be maximized as a function of the parameters $\boldsymbol{\theta}$, see [10], to obtain an estimate for the transition intensities. The same approach can be used for Markov chains using the probability $f(x|\boldsymbol{\theta}) = (P^t)_{ij}$.

In some cases, there may only be aggregate data available which contains just the number or the proportion of objects in each condition state. This is the least-detailed information as the state sequence of individual objects is not known to the modeler. The estimation of the transition parameters based on aggregate data requires special care, which is outside the scope of this article.

In the field of civil engineering, Markov chains have been used to model uncertain deterioration in a number of areas like pavement, bridge, and sewer system management. One of the first examples is the Arizona pavement management system [11], which inspired the Pontis bridge management system [12]. For a more complete review of applications in bridge management, see [5]. More recently, Markov chains have been applied to sewer system and water pipeline deterioration, see e.g., [13] and [14].

Brownian Motion with Drift. The Brownian motion with drift (see **Brownian Motion**) is a continuous-time stochastic process $\{X(t), t \geq 0\}$ for which $X(t)$ is normally distributed with mean μt and variance $\sigma^2 t$ for all $t \geq 0$. In the physical approach to reliability, a resistance modeled as a Brownian motion with drift alternately increases and decreases. For this reason, the Brownian motion is often inadequate in modeling deterioration which is monotone. On the other hand, it has certain mathematical advantages. For example, explicit expressions are available for the probability distribution of the first-passage time to zero of strength minus stress, when stress and strength are assumed to be independent Brownian motions with drift [15] (see **Stress–Strength Model**).

Compound Poisson Process. Mercer and Smith [16] may have been the first to model deterioration as a stochastic process. In particular, they propose to model deterioration as a compound Poisson process. A compound Poisson process is a monotone stochastic process with independent and identically distributed deterioration increments which occur according to a Poisson process (see **Poisson Processes**). They define failure as the event in which the deterioration reaches such a level that the object is considered to be worn out completely. Probability distributions of the time of failure (lifetime) of objects subjected to a sequence of shocks occurring randomly in time as events in a homogeneous or a nonhomogeneous compound Poisson process are further studied in [17] and [18–20], respectively.

Lévy Process. Roughly put, continuous-time stochastic processes with independent and stationary increments, and with right-continuous sample paths having left limits are Lévy processes (see **Lévy Processes**). In mathematical terms, a stochastic process has stationary increments if the probability distribution of the increments $X(t+h) - X(t)$ depends only on h for all $t, h \geq 0$. Every Lévy process may be written as a sum of a Brownian motion, a deterministic part (linear in time), and an integral of compound Poisson processes, where all the contributing processes are mutually independent. The sample paths of a Lévy process are discontinuous with probability one if the process is monotone, because such a process can be decomposed into a linear part plus an integral of compound Poisson processes [21]. The

sample paths of a Brownian motion are continuous with probability one.

Gamma Process. A gamma process is a monotone stochastic process with independent, nonnegative increments having a gamma distribution with an identical scale parameter [21, 22]. Like the compound Poisson process, the gamma process is a jump process. Compound Poisson processes have a finite number of jumps in finite time intervals, whereas gamma processes have an infinite number of jumps in finite time intervals. The former are suitable for modeling usage such as damage due to sporadic shocks and the latter are suitable for describing gradual damage by continuous use. In the presence of inspection data, the advantage of the gamma process over the compound Poisson process is evident: measurements generally consist of deterioration increments rather than of jump intensities and jump sizes.

As far as the authors know, Abdel-Hameed [23] was the first to propose the gamma process as a proper model for deterioration occurring random in time. The gamma process is suitable to model gradual damage monotonically accumulating over time in a sequence of tiny increments, such as concrete creep [24], corrosion [5, 25], wear, fatigue, crack growth, erosion, swell, degrading performance index, and so on (*see Physical Degradation Models*). The gamma deterioration process was successfully applied to model condition-based maintenance (*see Maintenance Optimization*). For an overview, we refer to [26].

In mathematical terms, the gamma process is defined as follows. A random quantity X has a gamma distribution with shape parameter $v > 0$ and scale parameter $u > 0$ if its probability density function is given by

$$\text{Ga}(x|v, u) = \frac{u^v}{\Gamma(v)} x^{v-1} \exp\{-ux\} I_{(0,\infty)}(x) \quad (4)$$

where $I_A(x) = 1$ for $x \in A$ and $I_A(x) = 0$ for $x \notin A$, and $\Gamma(a) = \int_{t=0}^{\infty} t^{a-1} e^{-t} dt$ is the gamma function for $a > 0$. Furthermore, let $v(t)$ be a nondecreasing, right-continuous, real-valued function for $t \geq 0$, with $v(0) \equiv 0$. The gamma process with shape function $v(t) > 0$ and scale parameter $u > 0$ is a continuous-time stochastic process $\{X(t), t \geq 0\}$ with the following properties: $X(0) = 0$ with probability one, $X(\tau) - X(t) \sim \text{Ga}(v(\tau) - v(t), u)$ for all $\tau > t \geq 0$,

and $X(t)$ has independent increments. If $X(t)$ is a gamma process with shape function $v(t)$ and scale parameter u , then its expectation and variance are given by

$$E(X(t)) = \frac{v(t)}{u}, \quad \text{Var}(X(t)) = \frac{v(t)}{u^2} \quad (5)$$

A component is said to fail when its deteriorating resistance, denoted by $R(t) = r_0 - X(t)$, drops below the stress s . We assume both the initial resistance r_0 and the stress s to be known. Let the time at which failure occurs be denoted by the lifetime T . Owing to the gamma-distributed deterioration, the lifetime distribution can then be written as:

$$\begin{aligned} F(t) &= \Pr\{T \leq t\} = \Pr\{X(t) \geq r_0 - s\} \\ &= \frac{\Gamma(v(t), [r_0 - s]u)}{\Gamma(v(t))} \end{aligned} \quad (6)$$

where $\Gamma(a, x) = \int_{t=x}^{\infty} t^{a-1} e^{-t} dt$ is the incomplete gamma function for $x \geq 0$ and $a > 0$. Equation (6) resembles a striking duality between space (deterioration) and time (lifetime) that makes the gamma-process model amenable to analysis. The lifetime distribution based on a gamma-process deterioration, given by equation (6), has an increasing failure rate as long as the shape function $v(t)$ is increasing in t . Abdel-Hameed [23] even took the stress–strength model in equation (6) a stage further by regarding the deterioration failure level $y = r_0 - s$ as a random quantity $Y > 0$ as well.

Under the assumption of modeling the temporal variability in the deterioration with a gamma process, the question which remains to be answered is how its expected deterioration increases over time. Empirical studies show that the expected deterioration at time t is often proportional to a power law:

$$E(X(t)) = \frac{v(t)}{u} = a t^b \quad (7)$$

for some physical constants $a > 0$ and $b > 0$ [4, 24]. There is often engineering knowledge available about the power-law exponent b in equation (7). Çinlar *et al.* [24] show how a nonstationary gamma process ($b \neq 1$) can be transformed into a stationary gamma process ($b = 1$) and how the parameters of a stationary gamma process can be estimated using the method of **moments** and the method of

maximum likelihood. Bayesian estimation of a stationary gamma deterioration process under imperfect inspection can be found in [25]. An interesting extension of the univariate gamma process is the multivariate gamma process proposed by Ebrahimi [27].

A useful property of a stationary gamma process is that the gamma density $\text{Ga}(x|aut, u)$ transforms into an exponential density if $t = 1/(au)$. When the unit time length is chosen to be $\Delta = 1/(au)$, the increments of deterioration $D_i = X(i\Delta) - X((i-1)\Delta)$, $i = 1, 2, \dots$, are exponentially distributed with mean $1/u$. For this unit time, many probabilistic properties can be expressed in analytic form [28]. For example, the probability of failure in unit time i reduces to a shifted Poisson distribution with mean $1 + [y\mu]/\sigma^2$:

$$\begin{aligned} & \Pr\{X((i-1)\Delta) \leq y, X(i\Delta) > y\} \\ &= \frac{1}{(i-1)!} \left[\frac{y\mu}{\sigma^2} \right]^{i-1} \exp\left\{-\frac{y\mu}{\sigma^2}\right\}, \\ & i = 1, 2, 3, \dots \end{aligned} \quad (8)$$

For unit time length Δ and for all $n = 1, 2, \dots$, the joint probability density function of the independent increments $D_1, \dots, D_n$ can be written as a function of the sum of the increments $X_n = \sum_{i=1}^n D_i$ (being the l_1 -norm). The infinite sequence of random quantities D_n , $n = 1, 2, \dots$ is called l_1 -norm symmetric or l_1 -isotropic. Conversely, a scale mixture of stationary gamma processes follows directly from the minimal hypothesis of l_1 -isotropy; that is, if the order in which nonnegative deterioration increments occur is irrelevant (because we are only interested in their sum), the increments are exchangeable and l_1 -isotropic [28]. Note that independence is a special case of exchangeability. Exchangeability occurs when incorporating uncertainty in the average rate of deterioration by means of a scale mixture of stationary gamma processes (see **Subjective Life Models**).

The gamma process can be regarded as a compound Poisson process of gamma-distributed increments in which the Poisson rate tends to infinity and increment sizes tend to zero in proportion. Although the gamma process can be reformulated in terms of a limit of a compound Poisson process [22], it is not efficient to simulate a gamma process in such a way. This is because there are infinitely many

jumps in each finite time interval. A better approach for simulating a gamma process is simulating independent increments with respect to very small units of time (see Ref. 30 **Simulation of the Gamma Process**).

Wenocur [29] considers a very interesting extension of a stationary gamma process for the deterioration state under two different failure modes. An object is said to fail either when its condition reaches a failure level s or when a traumatic event (such as an extreme load) destroys it. Suppose that the traumatic events occur as a Poisson process with a rate (called the *killing rate*) which depends on the object's condition. In a time-dependent reliability analysis, the killing rate can be interpreted as the frequency of the load exceeding the resistance when the variability of the random loads is modeled by a peaks-over-threshold distribution and the stochastic process of load threshold exceedances is generated by a Poisson process with intensity λ [30]. In this situation, the cumulative distribution function of the lifetime can be written as

$$\begin{aligned} F(t) = 1 - E \left(\exp \left\{ - \int_{u=0}^t k(R(u)) du \right\} \right. \\ \left. \times I_{[s, r_0]}(R(t)) \right) \end{aligned} \quad (9)$$

where $R(t) = r_0 - X(t)$ is the resistance and $k(r)$ is the “killing rate” for resistance r . In our time-dependent stress–strength model, the killing rate is $k(r) = \lambda \Pr\{L > r\}$, which is exactly the physics-based frequency of the stress or load $L = l_0 + Z$ exceeding the strength r with Z the exceedance over threshold l_0 having a peaks-over-threshold distribution.

Aging and Positive Dependence

Introduction

In the fields of reliability and quality, vectors of nonnegative random variables, say $\mathbf{T} \equiv (T_1, \dots, T_n)$, most often arise as the natural objects to be analyzed; $T_1, \dots, T_n$ may for example, have the meaning of times to failure for the n components of a reliability system or for n similar items in a quality test for some new prototype, in an industrial production.

Concerning the joint probability distribution of $\mathbf{T}$, idealized models are defined by the conditions of stochastic independence among $T_1, \dots, T_n$ and exponentiality for their marginal distributions; in such cases computations can be rather simple, and often lead to explicit and close formulas for the solution of reliability problems.

In many cases of applied interest, however, such idealized conditions must be abandoned, being not realistic at all; lack of stochastic independence is expressed by the term *dependence*, whereas lack of exponentiality leads to what we generically express by the term *aging*.

In cases of aging and dependence, not only computation complexity considerably increases but even the meaning and possible interpretations of the obtained results may sometimes become unclear or controversial. This scenario explains why the analysis of specific conditions of stochastic dependence and of probability distributions with special aging properties, and related implications have become issues of central interest in the fields of reliability and quality. The basic notions of dependence and of aging had been already singled out during 1950s to 1960s of the twentieth century see in particular [1–3]; later, in the subsequent decades there was in the literature a real explosion of other specific definitions. Parallel to that, several probabilistic models emerged from applications, which gave rise simultaneously to conditions of aging and positive dependence. A considerable part of literature about these topics concerns the possible applications of different notions of aging and dependence to special models; this is typically done to obtain useful inequalities in reliability and quality evaluations.

The relevant literature in these fields is by now really very wide and it is outside the scope and possibility of this article to provide a satisfactory review of it. The purpose here is, rather, to present a discussion about some aspects of the relations existing between aging and positive dependence, of substantial character or just of formal type. This will be essentially performed in the section titled “Multivariate Aging and Relations between Aging and Positive Dependence”, where also some definitions are recalled and some remarks are presented specifically concerning multivariate aging. In the next section we recall some basic facts and notation about stochastic orderings and univariate aging, whereas the section titled “Notions of Positive Dependence” will provide a brief overview about notions of positive dependence.

Some Basic Notions and Notation

Basic concepts of univariate aging are, in particular, IFR (*increasing failure rate*), DFR (*decreasing failure rate*), IFRA (*increasing failure rate in average*), DMRL (*decreasing mean residual life*), and NBU (*new better than used*). Several other concepts have also been defined, some among them arising as more or less direct generalizations of the former ones.

Among the basic concepts, many come out in a quite natural way when considering *stochastic comparisons* between distributions of *residual lifetimes* at different *ages* and/or monotonicity-type properties of *failure rate* or of *mean residual life* functions. First, to set notation, these notions are briefly recalled.

Let T be a *lifetime*, i.e. a nonnegative random variable with the meaning of a time to a top event (e.g., a time to a failure of a component in a system). Typically we will think of T as the lifetime of a device or a component D and assume that T admits a continuous distribution function with density function $f(t)$, i.e.,

$$P\{T \leq t\} = F(t) = \int_0^t f(u) du \quad (1)$$

We denote by $\bar{F}$ the *survival function* and by $\lambda(t)$ the *failure rate function*:

$$\bar{F}(t) = 1 - F(t) \quad (2)$$

$$\lambda(t) = \frac{f(t)}{\bar{F}(t)} \quad (3)$$

2 Aging and Positive Dependence

so that we can also write

$$\lambda(t) = \lim_{\delta \rightarrow 0} \frac{P\{T \leq t + \delta | T > t\}}{\delta} \quad (4)$$

$$\overline{F}(t) = \exp\{-\Lambda(t)\} \quad (5)$$

where

$$\Lambda(t) = \int_0^t \lambda(u) du \quad (6)$$

is the *cumulated hazard rate function*. When T admits a finite expected value $\mathbb{E}(T)$, we define the mean residual life function as

$$\mu(t) = \mathbb{E}(T - t | T > t) \quad (7)$$

where, for fixed t , $\mathbb{E}(T - t | T > t)$ is the *average remaining life* for D , if survived until time t .

A *stochastic comparison* is a notion of ordering between two probability distributions. Stochastic comparisons generally have revealed to be important tools in statistic and applied probability; they can in particular be used for giving definitions and for formalizing results concerning aging and dependence. A basic reference is [4]; see also [5–7]. Most important univariate notions for our purposes here are the *Ordinary* (or *Usual*), the *Hazard Rate*, the *likelihood ratio*, and the *mean residual life* stochastic orderings (respectively denoted by $\leq_{st}$, $\leq_{hr}$, $\leq_{lr}$, $\leq_{mrl}$). See e.g., [4] for definitions and basic properties; in particular it is shown that the following chain of implications holds:

$$\leq_{lr} \implies \leq_{hr} \implies \leq_{st}; \quad \leq_{hr} \implies \leq_{mrl} \quad (8)$$

An aspect of basic interest when studying conditions of univariate aging generally concerns the probabilistic behavior of the residual lifetimes at different *ages*. In other words attention is focused on the conditional survival probability

$$P(T > t + \tau | T > t) = \frac{\overline{F}(t + \tau)}{\overline{F}(t)} \quad (9)$$

when considered, for fixed $\tau > 0$, as a function of the age t .

In the cases when the probability distribution of T does admit a density function, and then a failure rate function $\lambda(t)$, one can also equivalently write

$$P(T > t + \tau | T > t) = \exp \left\{ - \int_t^{t+\tau} \lambda(u) du \right\} \quad (10)$$

We say that (the distribution of) a lifetime T is IFR when the function $\lambda(t)$ is nondecreasing, and that it is DFR when $\lambda(t)$ is nonincreasing. As the borderline case, we have that T is *exponentially distributed* if and only if $\lambda(t)$ is constant all over the half line $[0, +\infty)$. For fixed τ , the conditional survival probability $P(T > t + \tau | T > t)$ is a nonincreasing function of the age t , if T is increasing failure rate. Notice that, in the cases when T admits a density f , and then the failure rate λ , the two conditions are actually equivalent; but we can consider of course monotonicity conditions for $P\{T > t + \tau | T > t\}$ also for cases when T does not admit a density. A dual argument holds for the notion of decreasing failure rate.

IFR is a notion of *positive aging* whereas DFR describes *negative aging*.

Other notions of positive and negative aging studied in the literature are defined as natural generalizations, in some other sense, of the notions of IFR and DFR, respectively. A very important notion, for instance, is the one of *NBU*: T is NBU when, for any $t > 0$ and $\tau > 0$, it is $P(T > t + \tau | T > t) \leq P(T > \tau)$.

Using the language of stochastic orderings, the IFR property is expressed by the condition that the distribution of the residual lifetime $T - t'$, conditional on $\{T > t'\}$, is stochastically greater (with respect to the ordinary stochastic ordering) than that the distribution of $T - t''$, conditional on $\{T > t''\}$, for any pair $0 \leq t' < t''$. Following this line, one can characterize other notions of aging for univariate distributions, by employing other notions of stochastic ordering or by setting different conditions on t', t'' .

A detailed account is given by Shaked and Shanthikumar in [4]; an account of most recent literature is provided, among more material, in the review provided by Lai and Xie [8].

The meaning of the basic notions of univariate aging, and their interest in obtaining useful inequalities, are very clear. In particular, as basic problems in the field of reliability, one has often to decide if in specific situations it is convenient to adopt procedures of *preventive maintenance* or of **burn-in**; if so one has, furthermore, to study the problem of the optimization of such procedures; the notions of aging have a fundamental role in such a kind of analysis (see [3, 9–13] for basic references).

In the analysis of aging, a key role is obviously played by the concept of time. Thus, in a genuine probabilistic approach, it is generally fruitful, and in

some cases compulsory, to study models of aging from the point of view of the theory of stochastic processes; in particular the theory of counting processes [14] and stochastic filtering with the observations of counting processes (see [15]) is to be taken into account for a rigorous and general development of reliability problems; see in particular [16–22]. Related to this frame it is important, before concluding this section, to mention that the concept of failure rate of a lifetime T is associated in a natural way to a stochastic process as follows: consider the counting process (actually a jump process with only one jump of size 1 at the random time T) defined by the position

$$X_t = \mathbf{1}_{\{T \leq t\}}, \quad t \geq 0 \quad (11)$$

The stochastic process defined by

$$\tilde{\lambda}_t = (1 - X_t)\lambda(t), \quad t \geq 0 \quad (12)$$

is the *stochastic intensity* of the process $\{X_t\}_{t \geq 0}$, with respect its *internal history*, i.e., the intensity of failure assigned at time t on the basis of the only information about whether it is $\{T > t\}$ or $\{T \leq t\}$.

Generally, the flow of available information may, however, be richer than that; the point process approach allows for a formalized study about the changes in the failure rate when passing from one to another level of information.

It is a central point in our discussion that, along with stochastic intensity, the aging properties too do depend on the flow of information.

Another important issue concerning failure rate functions is the generalization of the univariate concept to the multivariate case. Several different definitions have been presented in the relevant literature, depending on the special type of problems or application to be dealt with; see in particular [23–26]. A very natural and useful multivariate extension leads to the definition of *multivariate conditional hazard rate* (m.c.h.r.) functions, that has been analyzed in [25, 26]. Such a definition also can be directly related to stochastic intensities of some counting processes with a finite number of jumps.

For an ordered subset $I = \{j_1, \dots, j_{|I|}\} \subset \{1, 2, \dots, n\}$, let $|I|$ denote the number of elements of I and $\bar{I}$ denote the complement of I ; $\mathbf{T}_I$ denotes the vector of lifetimes $(T_{j_1}, \dots, T_{j_{|I|}})$; $\mathbf{e}$ denotes a vector with an appropriate number of coordinates all equal to 1 so that, for $t > 0$, it is $t\mathbf{e} = (t, t, \dots, t)$; furthermore,

for $0 < t_{j_1} \leq \dots \leq t_{j_{|I|}} \leq t$ the symbol

$$\{\mathbf{T}_I = \mathbf{t}_I; \mathbf{T}_{\bar{I}} > t\mathbf{e}\} \quad (13)$$

stands for the observation

$$T_{j_1} = t_{j_1}, \dots, T_{j_{|I|}} = t_{j_{|I|}}; T_j > t, j \in \bar{I} \quad (14)$$

For $I \subset \{1, 2, \dots, n\}$, $j \notin I$, $t > 0$, $0 < t_{j_1} \leq \dots \leq t_{j_{|I|}} \leq t$, the m.c.h.r. function $\lambda_{j|I}(t_{j_1}, \dots, t_{j_{|I|}})$ is defined by

$$\begin{aligned} &\lambda_{j|I}(t_{j_1}, \dots, t_{j_{|I|}}) \\ &= \lim_{\delta \rightarrow 0} \frac{P\{T_j \leq t + \delta | \mathbf{T}_I = \mathbf{t}_I; \mathbf{T}_{\bar{I}} > t\mathbf{e}\}}{\delta} \end{aligned} \quad (15)$$

The m.c.h.r. functions can be defined when the joint distribution of lifetimes admits a joint **probability density function**. In such a case the density function can be easily obtained from the knowledge of the set of m.c.h.r. functions and *vice versa*.

In the literature, several definitions of multivariate stochastic comparison (i.e., of partial ordering between two different multivariate probability distributions) have been introduced that arise as generalizations of corresponding univariate notions. So far, we have recalled that univariate stochastic orderings can be used to define and analyze notions of univariate aging. Both univariate and multivariate orderings also provide the language for defining several notions of positive dependence and multivariate aging.

Among several existing definitions of multivariate orderings, particularly relevant are the (multivariate) notions of *ordinary* stochastic ordering, *likelihood ratio* ordering, *hazard rate* ordering, between two n -dimensional random vectors $\mathbf{X}, \mathbf{Y}$. See again [4] for a complete review with definitions, relevant properties, and further details. We only mention here that, analogously to the univariate case, the chain of implications $\mathbf{X} \leq_{lr} \mathbf{Y} \implies \mathbf{X} \leq_{hr} \mathbf{Y} \implies \mathbf{X} \leq_{st} \mathbf{Y}$ holds. Let $\leq_*$ stand for any of the above three orderings $\leq_{st}, \leq_{hr}, \leq_{lr}$. It is to be noticed that, in the special case when both the vectors $\mathbf{X} \equiv (X_1, \dots, X_n)$ and $\mathbf{Y} \equiv (Y_1, \dots, Y_n)$ have stochastically independent components, it is $\mathbf{X} \leq_* \mathbf{Y}$ (in the multivariate sense) if and only if it is $X_i \leq_* Y_i, i = 1, \dots, n$, in the univariate sense.

Notions of Positive Dependence

Mathematically, a property of positive dependence relates to one multivariate probability distribution for a vector of random variables; from a statistical viewpoint, this is a property that describes a tendency of the different random variables to assume concordant values.

Historically, the first such notion introduced in the statistical literature, as it is very well known, is the one of *positive correlation* defined by the condition that the **covariance** $Cov(X, Y)$, between two random variables X, Y , is nonnegative. Many more notions of positive dependence have been introduced along the twentieth century, but the concept of covariance continued to play an important role, at the level of giving definitions or studying implications of such notions. For reliability uses, in particular, a very important issue in this direction is the property of *association*. A vector of lifetimes $\mathbf{T} = (T_1, \dots, T_n)$ is associated if the two random variables $\varphi(\mathbf{T}), \psi(\mathbf{T})$ are positively correlated, i.e., $Cov(\varphi(\mathbf{T}), \psi(\mathbf{T})) \geq 0$, for pairs of functions $\varphi, \psi : \mathbb{R}^n \rightarrow \mathbb{R}$, with φ, ψ increasing in each coordinate and such that the covariance $Cov(\varphi(\mathbf{T}), \psi(\mathbf{T}))$ is well defined. It is interesting to mention that, in a natural way, the concept of association also has been raised in the fields of statistical mechanics and interacting particle systems (see e.g., [27]). It is well known among the reliability community that this concept has a very important role in the analysis of **coherent systems** (see in particular [3, 28, 29]). This is because of the following structural properties:

1. Any subset of a set of associated random variables is associated.
2. The union of two stochastically independent subsets of associated random variables is associated.
3. Any single random variable is associated.
4. Random variables obtained as different increasing functions of a same set of associated random variables give rise to an associate set.

A further idea that has a pervasive, and unifying, role in defining and analyzing positive dependence is, once again, that of stochastic comparisons. This fact may manifest, however, under several different forms, some of which are listed henceforth.

Take $n = 2$ random variables X and Z and consider a univariate stochastic ordering $\leq_*$ (where, this time, the symbol $\leq_*$ may stand for $\leq_{st}, \leq_{hr}, \leq_{lr}$,

mentioned in the section titled “Some Basic Notions and Notation”, or for other univariate notions). Conditions of the type

$$\bar{F}_X(\cdot | Z = z') \leq_* \bar{F}_X(\cdot | Z = z''), \quad \text{for } z' < z'' \quad (16)$$

$$\bar{F}_X(\cdot | Z > z') \leq_* \bar{F}_X(\cdot | Z > z''), \quad \text{for } z' < z'' \quad (17)$$

or

$$\bar{F}_X(\cdot | Z \leq z') \leq_* \bar{F}_X(\cdot | Z \leq z''), \quad \text{for } z' < z'' \quad (18)$$

are called *conditions of stochastic monotonicity* of X with respect to Z , and actually define properties of positive dependence for the pair (X, Z) .

As instances of that, we can cite in particular the following two concepts.

X is *stochastically increasing in Z* if, for any x , the function

$$P(X > x | Z = z) \quad (19)$$

is nondecreasing as a function of the variable z . X is *left tail decreasing in Z* if, for any x , the function

$$P(X > x | Z \leq z) \quad (20)$$

is nondecreasing as a function of the variable z . In these two cases, then, $\leq_*$ stands for the ordinary stochastic ordering.

Possibly using multivariate stochastic orderings, conditions of stochastic monotonicity can emerge in the characterization of some notions of positive dependence, or at least in providing necessary or sufficient conditions for them, also for the case with $n > 2$.

Other forms to express positive dependence are based on the comparison, with respect to some multivariate ordering, of the actual joint distribution with the distribution characterized by the same univariate marginals and stochastic independence among the variables. A very simple, and illuminating, example of this is provided by the concept of *positive quadrant dependence* (PQD) for a pair of lifetimes X, Y : this is expressed by the condition

$$\begin{aligned} \bar{F}(x, y) &= P\{X > x, Y > y\} \geq P\{X > x\} \cdot P\{Y > y\} \\ &= \bar{G}_X(x) \cdot \bar{G}_Y(y) \end{aligned} \quad (21)$$

i.e., for any choice of $x > 0, y > 0$, the two events $\{X > x\}, \{Y > y\}$, are positively dependent; it is then clear that this condition is implied by association of (X, Y) . In the multivariate case with $n > 2$, the notion of PQD can be extended to *positive upper orthant dependence* (PUOD) that, again, is a condition implied by association.

Defining concepts of dependence this way is strictly related to a more general fact: in several cases, a positive dependence property can be characterized in terms of the *connecting copula* or of the *survival copula* associated to the joint distribution at hand. From an analytical point of view, copulas are those functions $C : [0, 1] \times \dots \times [0, 1] \rightarrow [0, 1]$ that can be obtained as (restrictions to $[0, 1] \times \dots \times [0, 1]$ of) joint probability distribution functions of vectors of random variables $U_1, \dots, U_n$, having uniform marginal distributions.

Let $T_1, \dots, T_n$ be lifetimes with continuous marginal distribution functions $G_1, \dots, G_n$, marginal survival functions $\bar{G}_1, \dots, \bar{G}_n$, joint distribution function F and joint survival function $\bar{F}$. The connecting copula of the vector $\mathbf{T} = (T_1, \dots, T_n)$ is the copula C defined by the relation

$$F(x_1, \dots, x_n) = C(G_1(x_1), \dots, G_n(x_n)) \quad (22)$$

whereas the survival copula is the copula $\hat{C}$ defined by the relation

$$\bar{F}(x_1, \dots, x_n) = \hat{C}(\bar{G}_1(x_1), \dots, \bar{G}_n(x_n)) \quad (23)$$

As a simple instance of characterization of a positive dependence property in terms of copulas, it is immediate to check that PQD for a pair of lifetimes X, Y is equivalent to the condition $\hat{C}(u, v) \geq u \cdot v$ for their (bivariate) survival copula $\hat{C}$.

Many other conditions of positive dependence can be easily characterized in terms of the connecting copula or of the survival copula. For general reference books and other basic material about these issues see, in particular, [30–32] and references therein.

A different, formally very elegant, way to employ multivariate stochastic ordering concepts for the generation of positive dependence notions is as follows: it can happen that a multivariate stochastic ordering $\leq_*$ is not *reflexive* (for instance $\leq_{hr}$ and $\leq_{lr}$ are not: for a vector of lifetimes $\mathbf{T}$, it is not generally true that $\mathbf{T} \leq_{lr} \mathbf{T}$ nor that $\mathbf{T} \leq_{hr} \mathbf{T}$). For such a stochastic ordering, we can obtain a notion of

positive dependence by imposing that a vector $\mathbf{T}$ is such that $\mathbf{T} \leq_* \mathbf{T}$. In particular we say that $\mathbf{T}$ is *multivariate totally positive of order 2* (MTP_2) if $\mathbf{T} \leq_{lr} \mathbf{T}$ (see [33]) and that it is *hazard rate increasing upon failure* (HIF) if $\mathbf{T} \leq_{hr} \mathbf{T}$ (see [34]). The former notion implies the latter one; both of them imply association. Formally, the notion of MTP_2 has properties that mirror those of association mentioned above, even if it gives rise to a much more restrictive condition; in fact it is really a very strong notion, but also a very useful one, from several respects. For some uses of MTP_2 in Bayesian Statistics see Chapter 3 in [35] and some references therein.

In modern reliability theory it is often natural to look at different problems and models from the viewpoint of a *dynamic approach*. This amounts to take into consideration the evolution of the joint distribution of the residual lifetimes of surviving individuals, when time elapses and subsequent failures are progressively observed. Such an approach reveals to be necessary, for instance, in the following type of situations: we have to describe the probabilistic model for observable lifetimes $T_1, \dots, T_n$ of units that are subjected to similar environmental conditions, and such conditions change stochastically in time, giving rise to a nonobservable stochastic process.

Some dependence notions of *dynamic type* have been introduced in the literature to deal with such cases; often in these cases, the use of the concept of m.c.h.r. functions may emerge as natural.

A typical dynamic notion of dependence is the one of *weakened by failure*, introduced by Arjas and Norros in [36, 37]. This is a notion of positive dependence that implies association; it formalizes situations where, upon failure of a unit, the vector of residual lifetimes of the surviving components undergoes a decrease in the multivariate ordinary stochastic order sense.

The structure of this definition shows once again the possible role of the different notions of multivariate stochastic ordering in the description of conditions of positive dependence: in the above definition, the ordinary (multivariate) ordering can be replaced with other types of (multivariate) orderings to get different notions of positive dependence. In this respect, it is worthwhile pointing out that Shaked and Shanthikumar reobtained in this way some of the dependence properties mentioned above: when, in the above definition, the ordinary ordering is replaced

with the hazard rate ordering, in place of weakened by failure WBF we obtain HIF; when the ordinary ordering is replaced with the likelihood ratio ordering, in place of WBF we obtain MTP₂ (see [34]). This in particular shows that MTP₂ implies HIF and, in turn, HIF implies WBF; we then have the following chain of implications:

$$\begin{aligned} \text{MTP}_2 &\implies \text{HIF} \implies \text{WBF} \implies \text{Association} \\ &\implies \text{PUOD} \end{aligned} \quad (24)$$

Another notion (*Supportive Lifetimes*) can be obtained, similarly to above, in terms of the concept of (multivariate) cumulative hazard rate ordering.

The different notions of multivariate stochastic orderings and of positive dependence can take a specially expressive form, when the vector of lifetimes of concern is *exchangeable*, i.e., when the joint distribution of $T_1, \dots, T_n$ is the same of that of $T_{j_1}, \dots, T_{j_n}$ for any permutation $\{j_1, \dots, j_n\}$ of $\{1, \dots, n\}$; in particular, if $T_1, \dots, T_n$ are exchangeable, then they are identically distributed (not necessarily independent). De Finetti's theorem about exchangeable random variables says the following: if $T_1, \dots, T_n$ are exchangeable and constitute the initial segment of an exchangeable sequence $T_1, \dots, T_n, T_{n+1}, \dots$ then it is possible to construct a random variable Θ , such that $T_1, \dots, T_n$ are conditionally independent and identically distributed i.i.d., given Θ . It is easily seen that, in such a case, $T_1, \dots, T_n$ are positively correlated. Starting from this fact there has been, since a long time, a special interest in the analysis of positive dependence conditions for the case of exchangeability. In particular, e.g., characterizations of association for exchangeable variables were studied in [38]. A basic fact, concerning positive dependence and exchangeability is the study of the notion of *PDM*; a pair of random variables X, Y is PDM if they are conditionally i.i.d., given a random variable Θ (see [39, 40] and references therein). Several examples concerning aforementioned notions of multivariate orderings and positive dependence for the special case of exchangeability are discussed in [35].

Also, besides situations of exchangeability a central fact is that, more generally, positive dependence can be created by situations of conditional independence upon some nonobservable factors. In a few words, we can highlight the following: take lifetimes $T_1, \dots, T_n$ that are conditionally independent given a nonobservable scalar factor Θ ; for $j = 1, \dots, n$,

let $\bar{F}_j(\cdot|\theta)$, the conditional survival function of T_j given $\{\Theta = \theta\}$, be e.g., stochastically decreasing in θ , with respect to some fixed univariate stochastic order, then $\mathbf{T} = (T_1, \dots, T_n)$ has some property of positive dependence. A simple heuristic explanation goes as follows: observing high values for a subset of variables $\mathbf{T}_I$ induces to guess that Θ takes a low value; in turn, this induces to predict that the values taken by the remaining variables $\mathbf{T}_{\bar{I}}$ are high. In that case when nonobservable factors constitute a vector Θ , rather than being summarized by a scalar Θ , Θ must have some suitable property of positive dependence, to reach the same conclusion about positive dependence of $\mathbf{T}$.

All these are just general, roughly expressed facts; they are, however, related to fundamental aspects in the foundations of subjective probability and Bayesian statistics, as in particular very early discussed by Bruno de Finetti (see e.g., [41]).

The above heuristic argument can also be seen as the starting point to obtain several rigorous results. A basic step in such a direction is that, under suitable assumptions of stochastic monotonicity of $\mathbf{T}_I$ with respect to Θ , and for suitably ordered pairs $\mathbf{t}'_I, \mathbf{t}''_I$ the conditional distributions of Θ given the two different results $\{\mathbf{T}_I = \mathbf{t}'_I\}, \{\mathbf{T}_I = \mathbf{t}''_I\}$, are stochastic ordered (see in particular [42]).

Precise statements and specific definitions about positive dependence induced by conditional independence can be found in [43–47] and are also briefly recalled in the article **Mixture Models, Multivariate: Aging and Dependence**.

For other aspects of general interest related to positive dependence, see e.g., [43] and the volumes [48, 49]. For a very recent literature about new multivariate stochastic orderings and notions of positive dependence originated from them, see e.g., [50, 51], and references therein.

So far a few methods have been listed to “define” properties of positive dependence; one can wonder now: What is a property of positive dependence? Does there exist any axiomatic definition of what a notion of positive dependence is, in wider generality? A response to these questions has been given by Kimeldorf and Sampson in [52] for the case $n = 2$. They listed a set of axioms that a family of probability distributions should satisfy to give rise to a certain condition of positive dependence. Many important notions of dependence in fact do satisfy such axioms. In particular, related to something we

mentioned before, one of these axioms concerns the comparison of a bivariate distribution with the distribution corresponding to the case characterized by the same pair of marginals and stochastic independence. Different methods to extend that to the case $n > 2$, have been aimed more recently.

Once definitions of positive dependence have been defined and analyzed, the question arises, to understand, which are the multivariate probability models in the applications of interest that may manifest positive dependence. There is of course a very rich and interesting literature in this direction. Here, we will just limit ourselves to a brief discussion in the last part of the next section.

Multivariate Aging and Relations between Aging and Positive Dependence

Notions of *multivariate aging* concern vectors of lifetimes, like it does for notions of dependence; however, multivariate aging and dependence are different types of concepts. To understand the property of multivariate aging, we start by considering a vector of independent lifetimes. Fix first a univariate aging property $\sharp$ ($\sharp$ can stand e.g., for IFR, NBU, DFR, ...) and take n independent lifetimes $T_1, \dots, T_n$, with marginal survival functions $F_1, \dots, F_n$, respectively, so that

$$\bar{F}(t_1, \dots, t_n) = \bar{F}_1(t_1) \dots \bar{F}_n(t_n) \quad (25)$$

and let $\bar{F}_1, \dots, \bar{F}_n$ share the property $\sharp$. After that, it is analyzed which type of multivariate inequality is common to all the joint survival functions $\bar{F}$ that can be obtained in this way. We then pass to joint survival functions $\bar{F}$ of nonindependent lifetimes. We can finally assert that $\bar{F}$ satisfies a multivariate $\sharp$ property if it satisfies the previously considered multivariate inequality.

For instance, as a direct extension to the cases of dependence of a property valid for independent IFR lifetimes, the definition of multivariate increasing failure rate (MIFR) considered by Shaked and Shantikumar in [53, 54], is given as follows.

Compare two different observations

$$\{\mathbf{T}_I = \mathbf{t}_I; \mathbf{T}_{\bar{I}} > t\mathbf{e}\}, \{\mathbf{T}_I = \mathbf{t}'_I, \mathbf{T}_J = \mathbf{t}'_J; \mathbf{T}_{\bar{I} \cap \bar{J}} > t'\mathbf{e}\} \quad (26)$$

with $\mathbf{t}'_I \leq \mathbf{t}_I \leq t\mathbf{e}$, $t\mathbf{e} \leq \mathbf{t}'_J \leq t'\mathbf{e}$ and consider the vectors of the residual lifetimes $\mathbf{T}_{\bar{I} \cap \bar{J}} - t$, $\mathbf{T}_{\bar{I} \cap \bar{J}} - t'$.

Then $\mathbf{T}$ is *MIFR* if the joint distribution of $\mathbf{T}_{\bar{I} \cap \bar{J}} - t\mathbf{e}$, given the observation $\{\mathbf{T}_I = \mathbf{t}_I; \mathbf{T}_{\bar{I}} > t\mathbf{e}\}$ is stochastically larger than the joint distribution of the vector $\mathbf{T}_{\bar{I} \cap \bar{J}} - t'\mathbf{e}$, given the observation $\{\mathbf{T}_I = \mathbf{t}'_I, \mathbf{T}_J = \mathbf{t}'_J; \mathbf{T}_{\bar{I}} > t'\mathbf{e}\}$.

It is to be said that the general strategy to define properties of multivariate aging as described above, does not lead, of course, to a uniquely determined solution; in fact, still for the same notion $\sharp$, there are different possible inequalities that can be extended from the case of independence to that of stochastic dependence. As a matter of fact, for instance, several different concepts of MIFR have been presented and analyzed in the literature; see in particular [16, 55–58].

Further notions of MIFR have been considered in [59–62] in the frame of a Bayesian approach to reliability and for the special case of exchangeable lifetimes; such notions are related to the concept of Schur concavity (see [63]). A univariate survival function is IFR if and only if it is log concave; relying on this fact, it can be easily checked, in particular, that the joint survival function $\bar{F}$ of independent identically IFR distributed lifetimes is Schur concave. It was highlighted by Richard E. Barlow that this property is also maintained under mixtures: more precisely, the joint survival function of exchangeable lifetimes that are conditionally i.i.d., with respect to some nonobservable factors, is still Schur concave. This remark suggested to define a multivariate notion of IFR for exchangeable lifetimes by requiring the Schur concavity property for their joint survival function.

Let $T_1, \dots, T_n$ be the lifetimes of n different, but similar, components $D_1, \dots, D_n$ and let $T_1, \dots, T_n$ be exchangeable; for a vector of observed ages $t_1, t_2, s_3, \dots, s_n$, consider the conditional probabilities of extra survival

$$P\{T_1 > t_1 + \tau | \mathbb{D}\}, P\{T_2 > t_2 + \tau | \mathbb{D}\} \quad (27)$$

where

$$\mathbb{D} = \{T_1 > t_1, T_2 > t_2, T_3 > s_3, \dots, T_n > s_n\} \quad (28)$$

It is obvious that, for $t_1 < t_2$, it is

$$P\{T_1 > t_1 + \tau | \mathbb{D}\} \geq P\{T_2 > t_2 + \tau | \mathbb{D}\} \quad (29)$$

whenever $T_1, \dots, T_n$ are independent and obey the same IFR distribution; this amounts to say that, whatever survival data has been observed for $D_3, \dots, D_n$,

the elder, between the two components D_1, D_2 , is the one that has the smaller probability of surviving for an extra time τ . It is easy to show (see [61]) that, for exchangeable lifetimes more generally, such inequality remains equivalent to Schur concavity of the joint survival function, as in the case of i.i.d. lifetimes. Schur concavity of the joint survival function is then called a Bayesian notion of IFR (see also the discussion in [35]).

A main difference between the latter and the MIFR property of [53] stands in the fact that MIFR is defined in terms of a comparison between the residual lifetimes, for the same set of surviving components, at two different ages of them; in the inequality above, on the contrary, the residual lifetimes of two different (but exchangeable) components of different ages are compared at the same calendar time. In both the cases, two conditional distributions are compared; but, in the latter case, conditioning is performed with respect to a similar observed event; this allows one to discern the effects of aging and the effects of stochastic dependence. A further source of difference between the two types of definition is based on the fact that, in the definition of MIFR, the comparison is described in terms of a multivariate ordering.

As mentioned in the section titled “Some Basic Notions and Notations”, several natural notions of univariate aging have been defined; for some of those, corresponding multivariate extensions can be singled out by following, for instance, the logic that lead to the notion of MIFR and by using different types of multivariate stochastic orderings.

For exchangeable lifetimes (see [64]), many other notions of multivariate aging can be given in terms of univariate aging as follows. For a given univariate stochastic ordering $*$, we can define different notions of multivariate aging by comparing, in the $*$ sense, distributions of residual lifetimes $T_1 - t_1$ and $T_2 - t_2$, conditionally on different possible types of observed events; see [35] for a discussion about this approach; for a further review and further aspects of the Bayesian approach to Reliability, see also [8, 65].

A different logic that has been sometimes adopted in the definition of multivariate notions of aging is as follows: it is required that a distribution of joint lifetimes has a multivariate aging property $\sharp$ only if their univariate marginals have the corresponding (univariate) property $\sharp$ (see e.g., [66]).

In some cases, however, this requirement is not necessary; in particular when, due to the presence of nonobservable factors, dependence among observable lifetimes is explained by situations of learning about such factors; see also the discussions in [35, 62] (see **Mixture Models, Multivariate: Aging and Dependence**).

Before continuing the discussion, an important aspect that generally apply in the definition of any multivariate aging notion needs to be stressed. In any case, a multivariate aging notion $m\text{-}\sharp$ is seen as a multivariate extension of a corresponding univariate notion $\sharp$. For vectors of stochastically independent lifetimes $T_1, \dots, T_n$, the property $m\text{-}\sharp$ holds if and only if each $T_j (1 \leq j \leq n)$ satisfies the property $\sharp$ (e.g., see [54] for what specifically concerns the property of MIFR). In a few words, notions of multivariate aging for the joint distribution of several lifetimes substantially reduce to univariate **aging notions** for the marginals, when the lifetimes are independent.

We can then say that, just by definition, genuine conditions of multivariate aging manifest only in the cases of stochastic dependence. Thus multivariate aging and dependence are just two different, but concomitant, aspects of multivariate survival distributions.

On the other hand, also univariate aging of components is easily seen to be triggered by dependence in a natural way. Let $T_1, \dots, T_n$ be the lifetimes of dependent components $D_1, \dots, D_n$ and let us admit that, initially, $T_1, \dots, T_n$ have exponential (i.e., nonaging) marginal distributions. Consider then, at the calendar time $t > 0$, the conditional probability distribution of the residual lifetime $T_j - t$, given an observed history $\{\mathbf{T}_t = \mathbf{t}_t; \mathbf{T}_{\tilde{t}} > t\mathbf{e}\}$, where $j \in \tilde{t}$, i.e., j is an index such that D_j survived up to t . Generally, such conditional distribution is not exponential, anymore.

In applied models, in fact, many situations that give rise to positive dependence have been studied in detail to show how they also manifest (positive or negative) univariate aging. In turn, positive univariate aging combined with positive dependence is expected to create conditions of positive multivariate aging.

It is then an interesting and important issue, in quality and reliability, to understand possible substantial interactions existing between the phenomena of positive dependence, univariate aging, and multivariate aging. Such interactions are, however,

rather convoluted and general results are missing; this constitutes then a still open field of research. A major difficulty, of course, is associated to the fact that different approaches have been followed in defining multivariate aging and these points are further discussed briefly below.

Previously, we prefer to dwell on relations and analogies, between aging and dependence, that can be established at a conceptual or just at a formal level.

First, a conceptual aspect of fundamental importance that is common to aging and dependence is focused on. As well known, and was also recalled above, both dependence and aging properties may depend on the state of information we have on a vector of lifetimes; see articles [16, 18, 21, 22] for a general and rigorous treatment. As a very simple example we can consider here the case of the lifetimes $T_1, \dots, T_n$ of n similar components $D_1, \dots, D_n$ that work independently of each other and share a common “quality” Θ ; we suppose then that, when Θ is known to take a value θ , $T_1, \dots, T_n$ are i.i.d. with the same survival function $\bar{G}(\cdot|\theta)$; suppose also that $D_1, \dots, D_n$ are to work in a situation of wearout so that $\bar{G}(\cdot|\theta)$ is assumed to be IFR, for any possible value θ . Whenever we have a state of uncertainty about Θ and we look at Θ as a random variable with a probability density π of its own, then, in the unconditional distribution, $T_1, \dots, T_n$ are conditionally independent and, in particular, positively dependent by mixture; $T_1, \dots, T_n$ are not anymore independent, however. Simultaneously, also the IFR property of their marginal can be lost under mixture (see **Mixture Models, Multivariate: Aging and Dependence**). This example points out the following possibility: depending on the level of information, lifetimes $T_1, \dots, T_n$ can be independent, identically IFR distributed or can, alternatively, manifest positive dependence and some aspect of negative aging, in the marginal distribution.

Continuing the discussion about analogies between aging and dependence, we also must appreciate the role of concepts of stochastic ordering in the definitions of positive dependence, univariate aging, and multivariate aging. Univariate stochastic orders are used to define both univariate and (some) multivariate notions of aging. Multivariate stochastic orders can be used to define both notions of positive dependence and some of the notions of multivariate aging.

A concept that can also have formally a unifying role, at least for exchangeable lifetimes, is the one of *semicopula*. Let us limit ourselves to the case of $n = 2$ dimensions. As mentioned, several notions of dependence, for a pair of lifetimes, can be characterized in terms of their survival copula $\hat{C}$. Copulas are special cases of semicopulas. A bivariate copula, as said, is just a bivariate distribution function C with support on $[0, 1] \times [0, 1]$ and with uniform marginals; being a distribution function, C is increasing in each of the two variables and satisfies the rectangular inequality (see e.g., [31]). A semicopula is a function that satisfies all the properties of a copula except, possibly, the rectangular inequality; formally, we can extend the notions of dependence also to the field of semicopulas.

We can associate a semicopula A to a one-dimensional survival function $\bar{G}$, by formally defining, see [67],

$$A(u, v) = \bar{G} \left[\bar{G}^{-1}(u) + \bar{G}^{-1}(v) \right], \\ 0 \leq u \leq 1, 0 \leq v \leq 1 \quad (30)$$

It was an idea pointed out by Averous and Dortet-Bernadette, see [68], that (univariate) aging properties of $\bar{G}$ reflect into dependence properties of A (in [68], in particular, only cases in which A is a copula were considered).

Then univariate aging can be formally expressed as a property of dependence.

On the other hand, to an exchangeable bivariate survival function $\bar{F}$, with everywhere positive and strictly decreasing marginal survival function $\bar{G}$, one can associate a semicopula $B : [0, 1] \times [0, 1] \rightarrow [0, 1]$ defined as follows:

$$B(u, v) = \exp \left\{ -\bar{G}^{-1} \left(\bar{F}(-\log u, -\log v) \right) \right\} \quad (31)$$

so that

$$\bar{F}(x, y) = \bar{G} \left(-\log B(e^{-x}, e^{-y}) \right) \quad (32)$$

The function B is of interest in that it provides a tool to describe the family of the level curves of $\bar{F}$ by means of a semicopula, and for this reason it was introduced in [69]. It was also noticed in [69] that some of the bivariate aging properties introduced in the Bayesian approach are just properties of the

family of the level curves of $\overline{F}$ and can be translated into dependence properties of B .

For the same bivariate model $\overline{F}$, in this way, we have the following statements:

1. Some of the possible properties of dependence can be described in terms of dependence properties of the survival copula $\widehat{C}$.
2. Some of the possible properties of univariate aging can be described in terms of dependence properties of the semicopula A .
3. Some of the possible properties of bivariate aging can be described in terms of dependence properties of the semicopula B .

These facts allows one to give an axiomatic definition of “correspondence” among notions of dependence, univariate aging, and bivariate aging.

Let us, for instance, look at the condition of PQD that, as we saw in the section titled “Notions of Positive Dependence”, has the meaning of a property of positive dependence when imposed on the survival copula $\widehat{C}$. The same condition corresponds to the univariate aging property of new better than used NWU when imposed on the semicopula A ; it corresponds to a suitable bivariate aging property of bivariate NBU when imposed on the semicopula B .

Such a correspondence puts us in a position to analyze some interactions among properties of positive dependence, univariate aging, and bivariate aging. In [67], it was, e.g., shown that the combination of positive dependence and positive univariate aging imply positive bivariate aging, whereas the combination of positive dependence and negative bivariate aging imply negative univariate aging.

These relations can also be of interest in the analysis of the evolution of aging and dependence properties for residual lifetimes of surviving components, at the increase of their age. A sketch of this approach is presented in [70]; a more complete development could be the object of further research.

Obviously, these results are not generally true for other notions of multivariate aging; their interest is limited to the cases where the “Bayesian” notions can be applied and essentially they have been developed, so far, only for the cases of exchangeable lifetimes.

Other relations between positive dependence, multivariate and univariate aging have also been pointed out in the literature.

As mentioned, notions of multivariate aging defined according to the line considered e.g., in the paper [66] require corresponding properties of univariate aging for the marginal distributions, irrespective of dependence conditions.

Dynamic notions of positive multivariate aging considered in [17, 54] imply corresponding properties of positive dependence. In passing, it is to be noticed that these conditions of multivariate aging can be rather restrictive. This can happen, e.g., in the case of conditional independence; in such a case, in fact, positive dependence can likely manifest along with some aspect of negative univariate aging for the marginal distributions (*see also the discussion in Mixture Models, Multivariate: Aging and Dependence*).

Several papers in the current literature were devoted to analyzing relationships among dependence, univariate, and multivariate aging, under the specification of particular survival models, rather than from a conceptual and general point of view. For lack of room, we cannot review these types of analyses, here. In this respect, we just recall some general classes of models, that emerge for relevance of their applied interest, and that may simultaneously manifest phenomena of positive dependence and of aging.

Among models of interest, we find the multivariate mixture models, characterized by an assumption of conditional independence for the lifetimes $T_1, \dots, T_n$, given a random vector Θ of unobservable factors (*see Mixture Models, Multivariate: Aging and Dependence*). Owing to such an assumption, positive dependence is likely to be present along with some form of univariate aging.

Such models, where Θ is constant in time, can actually be looked at as very special cases of the more general situation where Θ is replaced by a stochastic process Θ_t and the observable lifetimes $T_1, \dots, T_n$ are conditionally independent given the history of Θ_t . This situation also appear in a great variety of cases of interest in the applications.

Shock models constitute relevant cases of the above situations; in shock models the process Θ_t is typically a (possibly marked) point process, that accounts for the arrival times and severity of the shocks. In **change-point models**, Θ_t can still be seen as a counting process, with only one jump corresponding to the instant of change point. Change-point models, however, are not generally seen as

special cases of shock models, in fact the impact of the change point on the failure rate of the surviving components can differ from that triggered by shocks.

All these models can be seen as special cases of the more general situation where the $T_1, \dots, T_n$ are the lifetimes of different components $D_1, \dots, D_n$ that work simultaneously and are influenced by a common environment acting on all the units; here we are thinking of situations of stochastically varying environments. It has been recognized since a long time that a similar varying environment acting on the different components induces some type of correlation among the components' lifetimes. The analysis of this type of correlation has then a long and still continuing history; some basic references are [71–75]. For more recent references, see e.g., [76, 77].

On the other hand, the interplay between aging and dependence (see e.g., [78]) and the analysis of the impact of random environmental situations and shocks on aging properties have also a long history; see for example [79–81] where it is shown how situations of PDM aging can be created simultaneously. Again, for the interplay between aging and stress shocks see [82] and some references therein.

Further interesting multivariate models that explain the simultaneous creation of aging and positive dependence phenomena are the so-called load-sharing models (see e.g., [54, 83]). In these cases the failure rates depend on the set of the surviving components. These are not really situations of varying environmental conditions; still a dynamic approach is appropriate and the probabilistic model for the vector of lifetimes is conveniently described in terms of the multivariate conditional hazard rates.

Realizing that, for multivariate survival models, there are strong interactions between aging and dependence is a very important issue when dealing with real applied problems. Situations of positive aging, for instance, may suggest to adopt procedures of preventive replacement on the different units; on the other hand, the presence of strong positive dependence among units suggests that the replacement policy cannot be decided at time 0; in fact it should be sequential and the time to the next replacement is to be reconsidered after each observed failure. In this type of problems, it is also important to remind that the properties of aging and those of dependence may be modified by a change in the information level: for the same set of components, for instance, the structure of the optimal replacement policy depends on

the state of information and on what we are able to observe; even the decision, whether it is convenient to adopt a replacement procedure or not may depend on the state of current information (see e.g., [84]).

Similar arguments are also to be taken into account when, in the presence of negative aging, we plan some politics of burn-in.

We cannot conclude this article without mentioning that, especially in the last few years, there has been an explosion of papers and books on topics related to positive dependence in the fields of insurance and mathematical finance (see e.g., [85–87]). Several models and properties studied in these frames, in particular in relation to the analysis of *interacting defaults*, are rather strictly related to the literature developed in the fields of quality and reliability.

Physical Degradation Models

Introduction

The focus within the reliability area has traditionally been on the collection and analysis of time-to-failure (TTF) data. High reliability implies few failures, so assessing and improving product/process reliability based on TTF data can be difficult. Accelerated life testing (ALT) can shorten the product life during test intervals by stressing the product beyond its normal use. However, ALT involves considerable amount of extrapolation. One should incorporate as much knowledge about the product as possible in designing the acceleration experiments.

Many physical systems degrade over time. Recent advances in sensing and measurement technologies are making it feasible to collect extensive amounts of data on physical **degradation** associated with components, systems, and manufacturing equipment. Davies [1] discusses a variety of engineering applications, types of degradation data, and recent developments in the area of condition monitoring and system maintenance. These cover data from vibration and acoustical monitoring, thermography, lubricant and wear debris analysis, and so on. Meeker and Escobar ([2], Chapters 14 and 21 and references therein) describe applications in luminosity of light bulbs, corrosion of batteries, semiconductor metal-oxide semiconductor (MOS) devices, and so on.

In practice, a number of subjects are under study. Degradation measurements of each subject are taken over time. The number of observation times and observation times themselves are allowed to vary across the subjects. These types of data are referred to as regular *degradation data*. For some applications, only one meaningful measurement can be taken on each test unit. The degradation measurement process destroys or changes the physical or mechanical characteristics of test units. This is known as *destructive degradation*. For example, the data from fatigue crack growth subject to loading cycles [3, 4] and bridge beams subject to erosion of chloride ion ingress [5] belong to regular degradation data. Data from the strength of adhesive bonds subject to environmental effects and internal erosion [6] are from destructive

degradation experiments since the test is destructive and strength can be measured only once on each unit.

When the amount of degradation reaches a pre-specified critical level D , failure occurs. Let T denote the TTF and $X(t)$ be the degradation process, then $T = \inf\{t : X(t) \geq D\}$. In many tests, the failure data is supplemented by degradation data. Degradation data are a very rich source of reliability information and offer many advantages over TTF data. The goal of this article is to present some common models for physical degradation. Specifically, we shall mainly discuss random-effect models and some Lévy process models. There is extensive literature on non-linear random-effect models (e.g., [7, 8]), and it is flexible and has been found quite useful in reliability applications. The Lévy processes such as Wiener process and gamma process have also been found useful as **degradation models**. These models lead to tractable forms for TTF distributions and thus we can make reliability inferences based on a combination of degradation and TTF data.

The paper is organized as follows. The section titled “Physical Degradation” gives some examples of physical degradation that provide useful motivation for degradation models. The section titled “Degradation Models” discusses two common physical degradation models and the reliability inferences drawn from them. In the section titled “An Illustrative Example”, we use a simulation example to illustrate that there are tremendous gains to be realized from degradation data. Finally we summarize the paper and describe some additional research topics.

Physical Degradation

In any given application, the problem context and appropriate subject matter knowledge must be used to model the underlying degradation mechanisms ([9] and [10] are good examples). For well-understood failure mechanisms, one may have a model based on physical/chemical theories that describe the underlying degradation process. Usually degradation models start with a deterministic description of the degradation process, often in the form of a differential equation. Then randomness can be incorporated into the model to describe the material parameters, component-to-component variability, initial conditions, and operating and environmental conditions.

2 Physical Degradation Models

Example 1: Automobile tire wear. If $\Lambda(t)$ is the amount of automobile tire tread wear at time t . This can be modeled simply by linear rate of degradation and wear rate is $d\Lambda(t)/dt = C$, then $\Lambda(t) = \Lambda(0) + Ct$, where $\Lambda(0)$ and C could be taken as constant for individual units but random from component-to-component.

Example 2: Fatigue crack growth. The prediction of crack growth accumulation is crucial for the reliability analysis of various materials in manufacturing. Let $\Lambda(t)$ be the crack size at time t and $\Delta K(\Lambda)$ be the stress intensity range, which is a function of the current crack size. A common used crack growth rate model is the Paris-rule model (e.g., [11]),

$$\frac{d\Lambda(t)}{dt} = C[\Delta K(\Lambda)]^m \quad (1)$$

where C and m are material properties. For example, when modeling a two-dimensional edge crack in a plate, $\Delta K(\Lambda) \propto \sqrt{\Lambda}$. Then we have

$$\Lambda(t) = \begin{cases} (C_0 + C_1 t)^{2/(2-m)} & m \neq 2 \\ C_3 e^{C_4 t} & m = 2 \end{cases} \quad (2)$$

where $C_i, i = 1, \dots, 4$ are constants which are functions of m . Note that different choices of m lead to different shapes of degradation paths.

Example 3: Current-gain degradation of bipolar transistors. In self-aligned polysilicon emitter transistors, a large electric field existing at the periphery of the emitter–base junction under reverse bias can create hot-carrier-induced degradation. Let Λ be the current gain, Burnett and Hu [12] studied a hot-electron degradation model,

$$\frac{d\Lambda(t)}{dt} = CG(\Lambda)I_R e^{-\phi/kT_e} \quad (3)$$

where ϕ is the critical energy needed for device damage, T_e is electron temperature, I_R represents the density of electrons, and $G(\Lambda)$ represents the dependence of degradation rate on existing damage. Assuming $G(\Lambda) \propto \Lambda^{-h}$, we have

$$\Lambda(t) \propto [t I_R e^{-\phi/kT_e}]^{1/(h+1)} \quad (4)$$

This relationship can be used to predict MOS device degradation dynamics.

Example 4: Photodegradation of polymeric materials. Excessive exposure of polymeric materials

leads to photodegradation failure. Let Λ be the total number of absorbed photons that effectively contribute to the photodegradation of a material during an exposure period. It has the form [13]

$$\Lambda(t) = \int_0^t \int_{\lambda_0}^{\lambda_1} E_0(\lambda, s)(1 - 10^{-A(\lambda, s)})\phi(\lambda) d\lambda ds \quad (5)$$

where λ_0 and λ_1 are the minimum and maximum photolytically effective UV–visible wavelengths, respectively, $A(\lambda, s)$ is the absorbance of sample at specified UV–visible wavelength and at time s , $E(\lambda, s)$ is the incident spectral UV–visible radiation dose to which a polymeric material is exposed at time s , and $\phi(\lambda)$ is the damage at wavelength λ relative to a reference wavelength. The overall photolytic damage to a polymeric material can be a linear, power, or exponential response of Λ .

Degradation Models

There are many factors that cause variability in the degradation curves and in the failure times. There are several approaches to modeling random degradation process in the literature. These include random-effect degradation models [4, 9, 10], stochastic process models such as Wiener process models [14–17], gamma process models [18–20], and compound **Poisson process** models [21], random shock process [22, 23], cumulative **damage models** [24], and multi-stage models [25]. For a general discussion of different degradation models, see Singpurwalla [26] and Meeker and Escobar [2]. We will mainly focus on the random-effect models and some nonhomogeneous Lévy process models.

Let $X_i(t)$ be the observed degradation path for unit i . Consider the nonlinear random-effect model

$$X_i(t) = \Lambda(t; \theta, \omega_i) + \epsilon_i(t) \quad (6)$$

where $\Lambda(t)$ is a smooth monotone function of t , θ is the population-level parameter characterizing degradation, ω_i is the random effect associated with subject i , and $\epsilon_i(t)$ is measurement error. In general, the degradation path $\Lambda(t; \theta, \omega_i)$ will be nonlinear and could be chosen by physical mechanism theory as discussed in the section titled “Physical Degradation”. For example, data from a linear random-effect model

is given by

$$X_i(t_j) = \omega_i t_j + \epsilon_i(t_j), \quad i = 1, \dots, n, \quad j = 1, \dots, m \quad (7)$$

Suppose we assume that ω_i 's are i.i.d. lognormal and $\epsilon_i(t_j)$'s are i.i.d. normally. TTF is defined as the first-passage time of the true degradation path $\omega_i t$ to the prespecified threshold D . The distribution function of TTF $T_i = D/\omega_i$ is $F_T(t) = P(\omega_i t > D) = 1 - F_{LN}(D/t)$, where F_{LN} is the lognormal distribution function. The TTF distribution function can be obtained analytically for simple models. For general nonlinear random-effect model in equation (6), Meeker and Escobar ([2], Chapter 21) also describe a simulation-based approach and the use of **bootstrap** methods for **estimation** and inference. Inference under the random-effect model (6) has been discussed in the literature, see, for example, Lu and Meeker [4] and Meeker *et al.* [27]. The common approach is to maximize the likelihood function directly. When the likelihood does not have a closed form, various approximations have been proposed [28] and are implemented in S-plus functions `lme` and `nmle`.

Next, we shall discuss two common nonhomogeneous Lévy processes models. First consider a nonhomogeneous Gaussian process $\{X(t) : t \geq 0\}$. Here, $X(t)$ represents the degradation measurement for an individual unit at time t . Let $\Lambda(t)$ be a continuous increasing function. The nonhomogeneous Gaussian process has the following properties: (a) the increments $\Delta X(t) = X(t + \Delta t) - X(t)$ are independent and (b) $\Delta X(t)$ has a **normal distribution** with mean $\Delta \Lambda(t) = \Lambda(t + \Delta t) - \Lambda(t)$ and variance $\sigma^2 \Delta \Lambda(t)$. Let $Z(t)$ be the basic Wiener process to have linear drift with $\nu = 1$. Then, we get the nonhomogeneous Gaussian process through time transformation as $Y(t) = Z(\Lambda(t))$. Thus, we can rewrite the model as

$$X(t) = \Lambda(t) + \sigma W(\Lambda(t)) \quad (8)$$

Note that this process $X(t)$ has continuous sample path and independent increments. The level crossing of the cumulative degradation threshold D by the process $X(t)$ can be obtained in terms of the inverse Gaussian (IG) distribution as $T_\Lambda = \Lambda^{-1}(T_{IG})$, where T_{IG} is $IG(D, D^2/\sigma^2)$. There is a huge literature on IG distribution and its applications ([29–31] and references therein). Assume that Λ belongs to a known parametric family from the knowledge of the degradation mechanism. For example, the family of power law curves $\Lambda(t; \nu, \beta) = \nu t^\beta$ can be used

to model increasing, constant, and decreasing degradation rates. An example with a finite asymptote is $\Lambda(t; \nu, \beta) = C(1 - \exp(-\nu t^\beta))$. These two families have been considered by Whitmore and Schenkelberg [17] in the context of accelerated degradation models. It is straightforward to get maximum-likelihood estimates of the parameters based on regular degradation data, since the differences of consecutive degradation measurements are independent normal random variables. In most cases this has to be done numerically. The Fisher information can be used, as usual, to get **confidence intervals** and test hypotheses.

Inference under nonhomogeneous gamma process is similar. The gamma process, $Y(t)$, has an independent increment $\Delta Y(t)$ which has gamma distribution $\text{Gam}(\Delta \Lambda(t), \alpha)$ with mean $\alpha \Delta \Lambda(t)$ and variance $\alpha^2 \Delta \Lambda(t)$. Unlike the Wiener process that has a non-monotone and continuous path, the gamma process has a monotone path and evolves on each time interval by means of an infinity of jumps. The TTF distribution can be obtained directly,

$$\begin{aligned} P(T < t) &= P(Y(t) > d) = 1 - G(d; \Lambda(t), \alpha) \\ &= I\left(\Lambda(t), \frac{d}{\alpha}\right) \end{aligned} \quad (9)$$

where $G(\cdot; \Lambda(t), \alpha)$ is the gamma distribution function with parameters $\Lambda(t)$ and α and $I(t, \alpha)$ is the upper incomplete gamma function, $I(t, \alpha) = \int_\alpha^\infty x^{t-1} e^{-x} dx / \Gamma(t)$. The unknown parameters are again estimated by maximizing the likelihood function.

An Illustrative Example

We will use simulated data to illustrate the parametric analysis and compare the estimators from degradation data and TTF data. We use a power law model $X(t) = \nu t^\beta + \sigma W(t^\beta)$ with $\nu = 1$, $\beta = 2$, and $\sigma^2 = 4$ be the true values of the parameters. Degradation data are simulated for $n = 40$ specimens at 10 time points $t_1 = 1, \dots, t_{10} = 10$. Figure 1(a) is the plot of this simulated data. Failure is defined when the degradation path crosses $D = 100$.

The maximum-likelihood estimators are given as: $[\hat{\nu}, \hat{\beta}, \hat{\sigma}] = [1.14, 1.96, 4.28]$ and the estimated standard errors are: 0.040, 0.096, and 0.345, respectively. Figure 1(b) shows the estimated $\Lambda(t)$ superimposed on the data (in dash-dotted line) and the pointwise

4 Physical Degradation Models

Figure 1 Simulated degradation data and estimated Λ and its pointwise 95% confidence intervals

Table 1 Maximum-likelihood estimators and their standard errors for degradation data and TTF data

Parameter	ν	β	τ
True	1.00	2.00	4.00
TTF data	0.24 (0.182)	2.62 (8.719)	6.41 (30.498)
Degradation data	1.14 (0.040)	1.96 (0.096)	4.28 (0.345)

95% confidence intervals. As we can see, the estimated $\hat{\Lambda}$ follows the data very well.

For the simulated data in Figure 1, suppose we observed only TTF data corresponding to the first-passage times above the threshold D , that is, the interval censored data. On the basis of this data, the MLEs are given by Table 1: $[\hat{\nu}, \hat{\beta}, \hat{\tau}] = [0.24, 2.62, 6.41]$, which are not good estimates compared to the estimates from degradation data. For the total 40 units, 3 units failed at interval $[t_8, t_9]$, 22 failed at $[t_9, t_{10}]$, and the other 11 failed after t_{10} . We do not have enough information to give good estimates of the parameters. We simulate the data 1000 times and the standard errors of these estimators from TTF are given in Table 1, which are very large. It is not uncommon to see situations where reliability engineers collect degradation data but convert them to “TTF” data and then do a standard Weibull or lognormal analysis with the pseudodata. Such converting is quite inefficient and there is tremendous gain to be realized from degradation data.

Discussion

An interesting extension for current degradation models is when we have information on covariates. For example, in accelerated degradation experiment, the stress level such as temperature is a **covariate**. Boulanger and Escobar [32] studied the design of accelerated degradation tests under the nonlinear random-effect model

$$X_{ij}(t) = \alpha_{ij} F(t, \xi_{ij}) + \epsilon_{ij}(t) \quad (10)$$

where $X_{ij}(t)$ is the degradation measurement at time t for the j th unit under stress condition i . F is a known continuous monotone increasing function of t with $F(0, \xi_{ij}) = 0$ and $F(\infty, \xi_{ij}) = 1$. Hence, α_{ij} measures the asymptote of the degradation level. Also, (α_{ij}, ξ_{ij}) are random coefficients with $E[\log \alpha_{ij}] = A + Bs_i$, where s_i is the i th stress level. If we have data from accelerated degradation tests, we may use model (10) to fit the data and estimate the unknown parameters. We can also use model (10) to develop the optimal degradation planning. The D -optimal plan is to maximize the determinant of Fisher information of the maximum-likelihood estimator of unknown parameters.

For nonhomogeneous Lévy processes models, Bagdonavicius and Nikulin [19] studied nonhomogeneous gamma process with covariates via an **accelerated life model** by replacing $\Lambda(t)$ by $\Lambda(te^{x^T \beta})$, where x is the covariate vector. Lawless and Crowder [20] treated scale parameter α in a gamma process as a

function of x to accommodate the covariate. Similar to **Cox** model, we may study the proportional mean model replacing $\Lambda(t)$ by $\Lambda(t)e^{x^T\beta}$ to incorporate the covariate information.

Another interesting issue to study is the optimal maintenance strategies for physical degradation systems. Good degradation models can be used as a tool to optimize maintenance decisions and to minimize the total maintenance cost of the system. Grall *et al.* [33] studied a predictive maintenance structure for a degradation system. They assumed the degradation process is a homogeneous gamma process and provided the maintenance policy to (a) determine whether the system should be replaced preventively or correctively, or whether the system should be left as is; (b) determine the time to the next inspection. There is a need for additional research to develop maintenance policy for other more complicated models.

Degradation and Failure

Introduction

Traditionally the failure time data are usually used for product reliability **estimation**. Failures of highly reliable units are rare and other information should be used in addition to censored failure time data. One way of obtaining complementary reliability information is to use higher levels of experimental factors or covariates (such as temperature, voltage, or pressure) to increase the number of failures and, hence, to obtain reliability information quickly. The *accelerated life testing* (ALT) of biotechnical systems is meant to be a simple practical method of estimation of the reliability of new systems without having to wait through the operating life of them. It is evident that the *extrapolating reliability* from ALT always carries the risk that the accelerating stresses do not properly excite the failure mechanism which dominates at operating (*normal*) stresses. Another way of obtaining this complementary reliability information is to measure some parameters (covariates) that characterize the aging of the product in time. In analysis of *longevity* of highly reliable complex industrial or biological systems, the **degradation** processes provide additional information about the *aging*, *degradation*, and *deterioration* of systems, and from this point of view the degradation data are really a very rich source of reliability information and often offer many advantages over failure time data. Degradation is the natural response for some tests, and it is also natural that with degradation data it is possible to make useful reliability and statistical inference, even with no failures. It is evident that it may be difficult or costly to collect degradation measures from some components or materials. Sometimes it is possible to apply the expert's estimation of the level of degradation. Sometimes it is possible to construct degradation models in which degradation is measured *without errors*, but there are also situations when the degradation data are obtained with measurement errors.

Degradation Process

In reliability there is considerable interest in constructing **covariate** $Z(\cdot)$ with some properties, depending on the phenomena in consideration, which

describe the *real* process of wear or the usage history up to time t , indicate the level of fatigue, degradation, and deterioration of a system, and may influence the rate of degradation, risk of failure, and reliability of the system. Statistical modeling of *observed degradation* processes can help to understand different real physical, chemical, medical, biological, physiological, or social degradation processes of aging. Information about *real degradation* processes helps us to construct degradation models, which permit us to predict the cumulative damage, and so on. According to the principal idea of degradation models, a *soft failure* is observed if the degradation process reaches a *critical threshold* z_0 . A soft failure caused by degradation occurs when $Z(t)$ reaches the value z_0 . The *moment*, T^0 , of soft failure is defined by the relation

$$T^0 = \sup\{t : Z(t) < z_0\} = \inf\{t : Z(t) \geq z_0\} \quad (1)$$

So it is reasonable to construct the so-called degradation models, based on some suppositions about the mathematical properties of the degradation process $Z(\cdot)$, in accordance with observed *longitudinal* data in the experiment. Both considered methods may be combined to construct the so-called joint degradation models. For this, it is enough to define a failure of the system when its degradation (*internal wear*) reaches a critical value or a traumatic event occurs. The joint degradation models form the class of models with **competing risk**, since for any item we consider two competing causes of failure: degradation, reaching a *threshold* (soft failure), and occurrence of a *hard* or *traumatic failure*. Let T^0 be the moment of traumatic failure of a unit. In the considered class of models, the *failure time* τ is the *minimum* of the moments of traumatic and soft failures, $\tau = \min(T^0, T) = T^0 \wedge T$. These models are also called *degradation-threshold-shock models*. For such models the degradation process $Z(t)$ can be considered as an additional time-dependent covariable, which describes the process of wear or the usage history up to time t . The degradation models with covariates are used to estimate reliability when the environment is dynamic (see [1–9], etc.). The covariates cannot be controlled by an experimenter in such a case. For example, the tire wear rate depends on the quality of roads, the temperature, and other factors. The problem of optimization of the values of these covariates is considered in [10], see also [11].

In [1] the use of so-called path models is proposed; the authors describe many different applications

2 Degradation and Failure

and models for *accelerated degradation* and Arrhenius analysis for data involving destructive testing. Meeker and Escobar [1] used *convex degradation models* to study the growth of fatigue cracks. They also used *concave degradation models* to study the growth of failure-causing conducting filaments of chlorine-copper compounds in printed-circuit boards [1]. *Concave degradation models* are used in [12] and [1] to describe degradation of components in electronic circuits.

In [1, 10, 13] *general degradation path models* are considered, according to which

$$Z(t) = g(t, \mathbf{A}) \quad (2)$$

here $\mathbf{A} = (\mathbf{A}_1, \dots, \mathbf{A}_r)$ is a random vector with positive components and the distribution function π of $\mathbf{A}$, and g is a specified continuously differentiable function in t , which increases from 0 to $+\infty$ when t increases from 0 to $+\infty$. For example, $g(t, a) = t/a$ (linear degradation, $r = 1$) or $g(t, a) = (t/a_1)^{a_2}$ (convex or concave degradation, $r = 2$). It is also supposed that, for each $t > 0$, the degradation path $(g(s, a) | 0 < s \leq t)$ determines in a unique way the value a of the random vector $\mathbf{A}$. Degradation in these models is modeled by the process $Z(t, \mathbf{A})$, where t is time and A is some possibly multidimensional random variable. In [14] *linear degradation models* are used to study the increase in a resistance measurement over time, and in [1] and [12] *convex degradation models* and *concave degradation models* are used to study the growth of fatigue cracks.

In [1, 2, 4, 9, 15] many different applications and models for *accelerated degradation* for data involving a destructive testing are described. The influence of covariates on degradation is also modeled in [1, 4, 5] to estimate reliability when the environment is dynamic. In [16] the parametric and semiparametric estimates in the model described in [4] are compared. The semiparametric analysis of several new degradation and failure time regression models without and with covariables is described in [6–8]. More information can be found in [1, 15, 17, 18].

Example: Degradation model with noise

Suppose that the lifetime of a unit is determined by the degradation process $Z(t)$ and the moment of its potential traumatic failure is T . Denote by T^0 the moment at which the degradation attains some critical

value z_0 . Then the moment of the unit's failure is $\tau = T^0 \wedge T$. To model the degradation–failure time process, we suppose that the real degradation process is modeled by the *general path model*:

$$Z_r(t) = g(t, \mathbf{A}) \quad (3)$$

where $\mathbf{A} = (A_1, \dots, A_r)$ is a random positive vector, and g is continuously differentiable function that increased in t . As remarked earlier, the real degradation process $Z_r(t)$ is often not observed, and we have to measure (to estimate) it. In this case, the *observed degradation process* $Z(t)$ is different from the real degradation process $Z_r(t)$. We supposed that we have the *degradation model with noise* according to which the *observed degradation process* is

$$Z(t) = Z_r(t)U(t), \quad t > 0 \quad (4)$$

where $\ln U(t) = V(t) = \sigma W(c(t))$, W is the standard *Wiener process* independent of A , and c is a specified continuous increasing function, with $c(0) = 0$. For any $t > 0$ the *median* of $U(t)$ is 1.

Using this model it is easy to construct a *degradation model with noise*. An important class of models based on degradation processes was developed recently in [19] and [4–6]. Wulfssohn and Tsiatis [19] proposed the so-called joint model for survival and longitudinal data measured with error, given by

$$\lambda_T(t|A) = \lambda_0(t)e^{\beta(A_1 + A_2 t)} \quad (5)$$

where $A = (A_1, A_2)$ follows bivariate **normal distribution**. On the other hand Bagdonavicius and Nikulin [7] proposed the model in terms of a conditional survival function of T given the real degradation process:

$$\begin{aligned} S_T(t|A) &= P\{T > t | g(s, A), 0 \leq s \leq t\} \\ &= \exp \left\{ - \int_0^t \lambda_0(s, \theta) \lambda(g(s, A)) ds \right\} \end{aligned} \quad (6)$$

where λ is the unknown **intensity function**, $\lambda_0(s, \theta)$ is from a parametric family of hazard functions. The distribution of A is not specified. This model states that the conditional hazard rate $\lambda_T(t|A)$ at the moment t given the degradation $g(s, A)$, $0 \leq s \leq t$, has the multiplicative form as in the famous **Cox model**:

$$\lambda_T(t|A) = \lambda_0(s, \theta) \lambda(g(s, A)) \quad (7)$$

If for example, $\lambda_0(s, \theta) = (1 + t)^\theta$ or $\lambda_0(s, \theta) = e^{t\theta}$, then $\theta = 0$ corresponds to the case when the

hazard rate at any moment t is a function of the degradation level at this moment. One can note that in the second model the function λ , characterizing the influence of degradation on the hazard rate, is nonparametric.

MIKHAIL NIKULIN

Accelerated Life Models

Introduction

In industry the failure time data are used for product reliability **estimation**. Failures of highly reliable units are rare and information other than traditional censored failure time data should be used. One way of obtaining this complementary reliability information is to apply the methods of the so-called *accelerated life testing* (ALT). The purpose of ALT is to give estimators of the main reliability characteristics under *usual* (normal, standard) stress (**design**) using data of *accelerated experiments* when units are tested at higher than usual stress conditions, that is, ALT is supposed to use higher levels of experimental time-varying factors or covariates (such as temperature, voltage, or pressure) to increase the number of failures and, hence, obtain reliability information more quickly. The so-called *accelerated life models* (ALMs) with time depending explanatory variables (stresses) are used to treat these data in ALT. The ALMs with dynamic environment give the possibility to include the effect of the usage history on the lifetime distributions of various units, subjects, items, populations, and so on. They are also well adapted to obtain the statistical inference in accelerated experiments with dynamic environment, when data are censored. All famous models such as **Cox** (proportional hazards) model, linear transformation model, frailty model, generalized proportional model, additive hazards model, accelerated failure time (AFT) model, and so on, are in the class of ALMs.

Suppose at first that the explanatory variable $x(\cdot) \in E$ is a deterministic time function:

$$x(\cdot) = (x_1(\cdot), \dots, x_m(\cdot))^T : [0, \infty) \rightarrow B \in \mathbf{R}^m \quad (1)$$

where E is a set of all possible stresses, $x_i(\cdot)$ is a univariate explanatory variable. If $x(\cdot)$ is constant in time, $x(\cdot) \equiv x = \text{const}$, we shall write x instead of $x(\cdot)$ in all formulas. We note E_1 a set of all constant in time stresses, $E_1 \subset E$.

Denote informally by $T_{x(\cdot)}$ the failure time under $x(\cdot)$ and by

$$S_{x(\cdot)}(t) = \mathbf{P}\{T_{x(\cdot)} \geq t\}, \quad t > 0, \quad x(\cdot) \in E \quad (2)$$

the *survival* or *reliability function* of $T_{x(\cdot)}$. The *hazard rate function* of $T_{x(\cdot)}$ under $x(\cdot)$ is

$$\begin{aligned} \alpha_{x(\cdot)}(t) &= \lim_{h \downarrow 0} \frac{1}{h} \mathbf{P}\{T_{x(\cdot)} \in [t, t+h) | T_{x(\cdot)} \geq t\} \\ &= -\frac{S'_{x(\cdot)}(t)}{S_{x(\cdot)}(t)} \end{aligned} \quad (3)$$

Denote by

$$A_{x(\cdot)}(t) = \int_0^t \alpha_{x(\cdot)}(u) du = -\ln\{S_{x(\cdot)}(t)\} \quad (4)$$

the *cumulative hazard function* of $T_{x(\cdot)}$.

We say that a stress $x(\cdot)$ is higher than a stress $y(\cdot)$ and we write $x(\cdot) > y(\cdot)$, if for any $t \geq 0$ the inequality $S_{y(\cdot)}(t) \geq S_{x(\cdot)}(t)$ holds and there exists $t_0 > 0$ such that $S_{y(\cdot)}(t_0) > S_{x(\cdot)}(t_0)$. In ALT the most used types of stresses are constant in time stresses, **step stresses**, progressive (monotone) stresses, cyclic stresses, and random stresses (see, e.g., Singpurwalla [1], Viertl [2], Nelson [3, 4], Meeker and Escobar [5], Lawless [6]). The most common case is when the stress is unidimensional, for example, pressure, temperature, voltage, but then more than one accelerated stresses may be used, and so on. The most frequently used time-varying stresses in ALT are step stresses: units are placed on test at an initial low stress and if they do not fail in a predetermined time t_1 , the stress is increased. If they do not fail in a predetermined time $t_2 > t_1$, the stress is increased once more, and so on. Thus step stresses have the form

$$x(u) = \begin{cases} x_1, & 0 \leq u < t_1, \\ x_2, & t_1 \leq u < t_2, \\ \dots & \dots \\ x_k, & t_{k-1} \leq u < t_k \end{cases} \quad (5)$$

where $x_1, \dots, x_k$ are constant stresses, $x_i \in E_1$. Sets of step stresses of the form equation (5) will be denoted by E_k , $E_k \subset E$. Let E_2 , $E_2 \subset E$, be a set of step stresses of the form

$$x(u) = \begin{cases} x_1, & 0 \leq u < t_1 \\ x_2, & u \geq t_1 \end{cases} \quad (6)$$

Sedyakin's Principle

In 1966, Sedyakin formulated his famous *physical principle in reliability*, which states that for two identical populations of units functioning under different

2 Accelerated Life Models

constant stresses x_1 and x_2 , two moments t_1 and t_2 are equivalent if the probabilities of survival until these moments are equal:

$$\begin{aligned} \mathbf{P}\{T_{x_1} \geq t_1\} &= S_{x_1}(t_1) = S_{x_2}(t_2) \\ &= \mathbf{P}\{T_{x_2} \geq t_2\}, \quad x_1, x_2 \in E_1 \end{aligned} \quad (7)$$

If after these equivalent moments the units of both groups are observed under the same stress x_2 , that is, the first population is observed under the step stress $x(\cdot) \in E_2$ of the form equation (6) and the second all the time under the constant stress x_2 , then for all $s > 0$

$$\alpha_{x(\cdot)}(t_1 + s) = \alpha_{x_2}(t_2 + s) \quad (8)$$

Using this idea of Sedyakin, it was proposed (see [7]) to consider one generalization of the Sedyakin's model to the case of any time-varying stresses by supposing that the hazard rate $\alpha_{x(\cdot)}(t)$ at any moment t is a function of the value of the stress at this moment and of the probability of survival until this moment:

$$\alpha_{x(\cdot)}(t) = g(x(t), A_{x(\cdot)}(t)), \quad x(\cdot) \in E \quad (9)$$

for some positive function g on $E \times \mathbf{R}^+$. This model is called the *generalized Sedyakin model* (GSM). Let us consider the meaning of the *rule of time-shift* in equation (9) in the case of the GSM when one applies the step stresses in equation (5) or equation (6). It is easy to show that if the GSM holds on E_2 then the hazard rate under the stress $x(\cdot) \in E_2$ satisfies the equality

$$\alpha_{x(\cdot)}(t) = \begin{cases} \alpha_{x_1}(t), & 0 \leq t < t_1 \\ \alpha_{x_2}(t - t_1 + t_1^*), & t \geq t_1 \end{cases} \quad (10)$$

where the moment t_1^* is determined by the equality $S_{x_1}(t_1) = S_{x_2}(t_1^*)$.

From this proposition it follows that for any $x(\cdot) \in E_2$ and for all $s \geq 0$

$$\alpha_{x(\cdot)}(t_1 + s) = \alpha_{x_2}(t_1^* + s) \quad (11)$$

This is the model on E_2 , proposed by Sedyakin [8].

If one takes a set E_k of stepwise stresses of the form equation (5), the GSM represents the famous *basic cumulative exposure model*, see Bhattacharyya and Stoejoeti [9], Nelson [3], Meeker and Escobar [5]. We note here that the Sedyakin model (SM) can be not appropriate in situations of periodic and quick

change of the stress level or when switch-up's of the stress from one level to the another can imply failures or shorten the life.

Accelerated Failure Time Model

The famous AFT model on E will be considered here. The AFT model holds on E if there exist on E a positive function r and on $[0, \infty)$ a survival function S_0 such that

$$S_{x(\cdot)}(t) = S_0\left(\int_0^t r\{x(u)\} du\right) \quad \text{for any } x(\cdot) \in E \quad (12)$$

where the survival function S_0 , called the *baseline survival function*, does not depend on x . It is the Sedyakin's prolongation of the AFT model for constant stresses, given by the formula:

$$S_x(t) = S_0\{r(x)t\} \quad \text{for any } x \in E_1 \quad (13)$$

For any fixed $x \in E_1$ the value $r(x)$ can be interpreted as the *timescale change constant* or the acceleration constant of reliability function. More about one AFT model can see, for example, Cox and Oakes [10], Lawless [6, 11], LuValle [12], Meekers and Escobar [5], Nelson [3, 4], Viertl [2], Singpurwalla [13], Duchesne [14], and so on.

Natural generalization of the AFT model, known as the *changing shape and scale* (CHSS) model (see [7]) holds on E if there exist two positive functions r and ν on E such that

$$S_{x(\cdot)}(t) = S_{x_0}\left(\int_0^t r\{x(\tau)\} \tau^{\nu(x(\tau))-1} d\tau\right), \quad x(\cdot) \in E \quad (14)$$

where x_0 is fixed stress, for example, design (usual) stress. Note that the variation of stress changes locally not only the scale but also the shape of distribution. This model is not in the class of the GSMs because the hazard rate

$$\alpha_{x(\cdot)}(t) = r\{x(t)\} q(A_{x(\cdot)}(t)) t^{\nu(x(t))-1} \quad (15)$$

depends not only on $x(t)$ and $A_{x(\cdot)}(t)$ but also on t . Generally it is recommended to choose $\nu(x) = e^{\gamma T x}$. Statistical analysis of this model is done in Bagdonavičius *et al.* [15]. If the functions $r(\cdot)$ and $S_0(\cdot)$ are unknown, we have a nonparametric

AFT (or CHSS) model. **Nonparametric analysis** of AFT and CHSS models can be found, for example, in Bagdonavičius and Nikulin [7], Bagdonavičius *et al.* [15]. The function $r(\cdot)$ can be parameterized. In this case we have a parametric AFT (or CHSS) model and the maximum-likelihood estimators of the parameters are obtained by almost standard way for any plans. If the baseline function S_0 is completely unknown, in this case we have a semiparametric model. In practice, often a baseline survival function S_0 is taken from some class of simple parametric distributions, such as Weibull, lognormal, log-logistic, and so on, and in this case we obtain the parametric AFT (or CHSS) model. An interesting family is obtained when S_0 belongs to the power generalized Weibull (PGW) family of distributions (see [7]). In terms of the survival functions, the PGW family is given by the next formula:

$$S(t, \sigma, \nu, \gamma) = \exp \left\{ 1 - \left[1 + \left(\frac{t}{\sigma} \right)^\nu \right]^{\frac{1}{\gamma}} \right\},$$

$$t > 0, \gamma > 0, \nu > 0, \sigma > 0 \quad (16)$$

If $\gamma = 1$ we have the Weibull family of distributions. If $\gamma = 1$ and $\nu = 1$, we have the exponential family of distributions. This class of distributions has very nice probability properties. All moments of this distribution are finite. In dependence of parameter values the hazard rate can be constant, monotone (increasing or decreasing), unimodal or $\cap$ -shaped, and bathtub or $\cup$ -shaped. Parametric AFT model was studied by many people, see, for example, Bagdonavičius *et al.* [16], Bagdonavičius *et al.* [17], LuValle [12], Nelson [3, 4], Meeker and Escobar [5], Lawless [6], Singpurwalla [1], and Shaked and Singpurwalla [18].

Competing Risks

Introduction

Suppose that units under study can experience any one of several distinct failure types, and that for each unit we observe both the time to failure and the type of failure. Here failure may, for example, correspond to breakdown of a mechanical component where there are several possible root causes for the failure, such as vibration and corrosion. While this is a typical case of a “competing risks” situation in reliability, the theory of competing risks does not originate from reliability theory. In fact, it can be traced back to David Bernoulli’s attempts in 1760 to disentangle the risk of dying from smallpox from other causes. This is indeed a classical example of competing risks, where individuals are subject to multiple causes of death. Similar applications occur in demography and actuarial science, usually under the name of multiple-decrement analysis.

Formal Definition of Competing Risks

Formally one observes the pair (T, C) where $T > 0$ is the time of failure and $C \in \{1, 2, \dots, k\}$ represents the type of failure. It is thus assumed that there are k different failure types, and that each failure can be classified as belonging to exactly one of the k types. Note that “failure” is used as a generic term and may in practice correspond to any event of interest depending on the application at hand. Also, “time” need not mean calendar time, but can in principle be any suitable measurement which is nondecreasing with calendar time, such as operation time, number of cycles, number of kilometers run, or length of a crack.

An intuitive way of describing a competing risks situation with k risks, is to assume that to each risk is associated a failure time T_j , $j = 1, \dots, k$. These k times are thought of as the hypothetical failure times if the other risks were not present, and they are referred to as *latent failure times*. When all the risks are present, the observed time to failure of the system is the smallest of these failure times along with the actual cause of failure. Thus by letting $T = \min\{T_1, \dots, T_k\}$ and $C = c$ if $T = T_c$, we observe

the pair (T, C) and we are back to the formulation of the previous paragraph. Note that it is assumed that the T_c for which minimum is attained is uniquely given.

Uses of Competing Risks in Reliability and Maintenance Studies

Crowder [1, Chapter 1] gives some simple examples of the uses of competing risks in reliability studies. One of these is taken from King [2] who studied data of breaking strengths of certain wire connections. Two types of failure were defined (so $k = 2$): breakage at the bonded end and breakage along the wire itself.

Modern reliability data banks usually distinguish between a large number of failure modes, which suggests the use of methods from the theory of competing risks. Cooke [3, 4] reviews some main styles in the design of *reliability databases*, as well as models and methods for the analysis.

Traditionally, competing risks were analyzed as if they were independent of each other. This assumption appears to be dubious in many reliability applications, however. Even if assumptions of stochastic independence may often be justified by the physically independent functioning of components, a dependence between risks may be introduced by many sources, for example, *load sharing* between components, shared working environment, manufacture, and maintenance.

A simple case of dependent risks occur in the case when a potential component failure at some time T_1 may be avoided by a **preventive maintenance** (PM) at time T_2 (see [4]). The assumption that T_1 and T_2 are independent is clearly unreasonable in this application, since the maintenance crew is likely to have some information regarding the component’s state during operation, and this insight is used to perform maintenance with the aim of avoiding component failure. Note that the observable result is the pair (T, C) , rather than the latent times T_1 and T_2 themselves, which are usually the times of primary interest. For example, knowing the distribution of T_1 , the true failure time distribution, could be the basis for *maintenance optimization*. However, as will be discussed later, the marginal distributions of the T_j are not identifiable from the observation of (T, C) alone, unless specific assumptions are made on the dependence.

2 Competing Risks

Basic Literature on Competing Risks

The recent book by Crowder [1] gives a comprehensive review of the theory and methods of competing risks. An older book devoted to the subject is David and Moeschberger [5]. Several standard books on reliability and survival analysis contain chapters on competing risks, for example, Lawless [6], Kalbfleisch and Prentice [7], Nelson [8], Bedford and Cooke [9], and Andersen *et al.* [10]. Among several review papers written on the subject we mention Gail [11] and Moeschberger and Klein [12].

Model Specification

The joint distribution of the pair (T, C) from an individual is completely specified by the subdistribution functions

$$F_j(t) = P(T \leq t, C = j); \quad t > 0, \quad j = 1, \dots, k \quad (1)$$

The corresponding subdensity functions, when they exist, are given by differentiation, $f_j(t) = F_j'(t)$. In the formulas given in the following, the ranges of t and j are clear and will be mostly suppressed.

The marginal distribution of T is given by the *cumulative distribution function*

$$F(t) = P(T \leq t) = \sum_{j=1}^k F_j(t) \quad (2)$$

or by the survival function $\bar{F}(t) = 1 - F(t)$. Note that here and in the sequel, a bar above a capital letter means that this is the (sub)survival function corresponding to the (sub)distribution function given without a bar. The marginal distribution of C is given by $\pi_j = P(C = j) = F_j(\infty)$.

The distribution of (T, C) can alternatively be specified by the subhazard functions, which when they exist are given by

$$\begin{aligned} \lambda_j(t) &= \lim_{\Delta t \rightarrow 0} \frac{P(T \leq t + \Delta t, C = j | T > t)}{\Delta t} \\ &= \frac{f_j(t)}{\bar{F}(t)} \end{aligned} \quad (3)$$

It follows that $\lambda(t) = \sum_{j=1}^k \lambda_j(t)$ is the hazard function of T . Moreover, from equation (3) it follows

that $f_j(t) = \lambda_j(t) \bar{F}(t)$ which by integration gives the useful connection

$$F_j(t) = \int_0^t \lambda_j(u) \bar{F}(u) du. \quad (4)$$

Next, defining the cumulative subhazard functions as $\Lambda_j(t) = \int_0^t \lambda_j(u) du$ it is seen that $\Lambda(t) = \sum_{j=1}^k \Lambda_j(t)$ is the cumulative hazard function of T . Thus we have

$$\bar{F}(t) = e^{-\Lambda(t)} = e^{-\sum_{j=1}^k \Lambda_j(t)} = \prod_{j=1}^k \bar{G}_j^*(t) \quad (5)$$

where

$$\bar{G}_j^*(t) = e^{-\Lambda_j(t)} \quad (6)$$

Note that $\bar{G}_j^*(t)$ is a survival function (possibly with an atom at infinity), but that it is not in general the distribution of any observable random variable (see, however, section title “Assuming Independent Risks”).

The subhazard functions $\lambda_j(t)$ have the intuitive interpretation as the failure rate from a specific cause conditional on survival up to time t . They are also known under the names of mode-specific or cause-specific hazard functions, and have in older literature been called *crude hazard rates*.

Latent Failure Time Representation

Consider again the representation where $T = \min\{T_1, \dots, T_k\}$ and $C = c$ if $T = T_c$, with c assumed uniquely given. Let the joint survival function of $T_1, \dots, T_k$ be $\bar{K}(t_1, \dots, t_k) = P(T_1 > t_1, \dots, T_k > t_k)$. Then the survival function of T can be evaluated as $\bar{F}(t) = \bar{K}(t, t, \dots, t)$. The subdensity functions can also be calculated directly from the joint survival function as

$$f_j(t) = - \left(\frac{\partial \bar{K}(t_1, \dots, t_k)}{\partial t_j} \right)_{t_1 = \dots = t_k = t} \quad (7)$$

and it further follows that

$$\lambda_j(t) = \frac{f_j(t)}{\bar{F}(t)} = - \left(\frac{\partial \log \bar{K}(t_1, \dots, t_k)}{\partial t_j} \right)_{t_1 = \dots = t_k = t} \quad (8)$$

Let the marginal survival function of T_j be denoted $\bar{G}_j(t) = P(T_j > t)$ and let the corresponding hazard rate function be $h_j(t) = -\bar{G}'_j(t)/\bar{G}_j(t)$. It is noted that in general $h_j(t)$ and $\lambda_j(t)$ are different and have different interpretations. While the former has traditionally been called the *net rate*, the latter is the *crude rate* as mentioned before. It will be seen later, however, that $h_j(t) = \lambda_j(t)$ for all $t > 0$ when the T_j are independent.

The Identifiability Problem

As already mentioned, the main interest in a competing risks analysis is often in the joint and marginal distributions of the latent failure times $T_1, \dots, T_k$. The classical problem of competing risks is, however, that the distribution of the observable pair (T, C) does not in general determine the distribution of the latent failure times. This means that there are several different joint distributions of $T_1, \dots, T_k$ which give rise to the same distribution of (T, C) . This fact, called *nonidentifiability* of the distributions of $T_1, \dots, T_k$, was noted by Cox [13] for the case of two failure causes, while Tsiatis [14] studied the general case.

The main result of Tsiatis [14] states that if the set of subdistribution functions $F_j(t)$ is given for some model with dependent risks, then there exists a unique model with independent risks yielding the same $F_j(t)$. This model is defined by the joint survival function

$$\bar{K}(t_1, \dots, t_n) = \prod_{j=1}^k \bar{G}_j^*(t_j) \quad (9)$$

where the $\bar{G}_j^*(t)$ are given by equation (6). Thus, one cannot know, from observations of (T, C) alone, which of the two models is correct, since they will both fit the data equally well.

How to Deal with the Identifiability Problem

In this section we consider ways of overcoming the identifiability problem under the latent failure time representation of competing risks. It should be stressed that this can only be done by imposing additional assumptions in the model. These may be of various kinds, but one should always have in

mind that under observation of the pair (T, C) , the assumptions will always be nontestable.

Assuming Independent Risks

The classical assumption is that the risks act independently, so that the latent failure times T_j are independent. It then follows from Tsiatis [14] (see above) that we have identifiability of the distributions in question (under regularity assumptions), meaning that the marginal distributions of the T_j now can be computed from the subdistribution functions $F_j(t)$. In practice this means that the marginal distributions can be estimated in a consistent manner from competing risks data. Furthermore, in the case of independence we can write $\bar{K}(t_1, \dots, t_k) = \prod_{j=1}^k \bar{G}_j(t_j)$ and hence it follows from equation (9) that $\bar{G}_j^*(t) = \bar{G}_j(t)$ and from equation (8) that $\lambda_j(t) = h_j(t)$. Thus in the independent risks case the $\bar{G}_j^*(t)$ are in fact the marginal survival distributions of the T_j .

Zheng and Klein [15] generalized the result on identifiability in the independent risks case by proving that the marginal distributions are identifiable when the dependence of the T_j is given by a known copula.

Computing Bounds for the Marginal Survival Functions

Peterson [16] gave bounds for the marginal distribution functions $G_j(t) = P(T_j \leq t)$ in terms of the observable subdistribution functions F_j . The bounds are given by

$$F_j(t) \leq G_j(t) \leq F(t) \quad (10)$$

which are easily verified. Peterson [16] showed, moreover, that these bounds are pointwise sharp. They are not, however, functionally sharp. In fact, Crowder [1] found that the functions $G_j(t) - F_j(t)$ need to be nondecreasing in addition to being nonnegative. Subsequently, Bedford and Meilijson [17] obtained the complete characterization of the feasible marginal distribution functions G_j for a given set of subdistribution functions F_j . They showed in particular that the condition that the functions $G_j(t) - F_j(t)$ are nonnegative and nondecreasing, is also sufficient, provided a subtle additional measure theoretic assumption is satisfied. Note that when F_j and G_j are differentiable, this leads to the inequality

$$f_j(t) \leq g_j(t) \text{ for all } t > 0 \quad (11)$$

4 Competing Risks

where $g_j(t)$ is the marginal density function of T_j . We use this inequality in the following example.

Example (adapted from Bedford and Meilijson [17]) Consider the model with $k = 2$ given by constant subhazard functions $\lambda_j(t) = \lambda_j$, $j = 1, 2$. In this case $F_j(t) = (\lambda_j/\lambda_+) (1 - e^{-\lambda_+ t})$ and $F(t) = 1 - e^{-\lambda_+ t}$, where $\lambda_+ = \lambda_1 + \lambda_2$. Assume now that T_1 has an exponential marginal distribution, so that $G_1(t) = 1 - e^{-\lambda t}$ for some λ . The upper bound of inequality (10) easily gives $\lambda \leq \lambda_+$. Further, the inequality (11) with $j = 1$ gives $\lambda_1 e^{-\lambda_+ t} \leq \lambda e^{-\lambda t}$ for all $t > 0$, which implies $\lambda \geq \lambda_1$ by letting $t \rightarrow 0$. Thus we have shown that any feasible value of λ must satisfy the inequality

$$\lambda_1 \leq \lambda \leq \lambda_+ \quad (12)$$

Bedford and Meilijson [17] in fact showed that the set of possible values is the half-open interval $[\lambda_1, \lambda_1 + \lambda_2)$. Note that an assumption that T_1 and T_2 are independent leads to $\lambda = \lambda_1$. The example therefore shows that the independence assumption leads to the most optimistic value of the failure rate λ among the ones that are possible when the dependence is not specified. Williams and Lagakos [18] proved a corresponding result in a more general setting.

Parametric Identifiability

Note that the meaning of identifiability of marginal distributions as discussed above has been in the nonparametric sense that the marginal distribution functions G_j can be derived in terms of the subdistribution functions F_j . If a parametric model is specified for the latent failure times, then the identifiability problem is a completely different one since it now has to do with identification of a finite set of parameters. Crowder [1, Chapter 7.7] and Moeschberger and Klein [12] review models for which identifiability holds (see section title “Modeling of Latent Failure Times”).

Modeling of Competing Risks

Modeling of subdistributions

Mixture models. These are models given by specifying subdistribution functions of the form $F_j(t) =$

$\pi_j Q_j(t)$ for given (parametric) distribution functions $Q_j(t)$ and weights π_j with $\sum_{j=1}^k \pi_j = 1$. An example is the Weibull version where $\bar{Q}_j(t) = \exp\{-(t/\theta_j)^{\alpha_j}\}$.

Modeling subhazard functions. Another common approach is to assume parametric models for the subhazard functions, for example using Weibull hazards, $\lambda_j(t; \alpha_j, \theta_j) = (\alpha_j/\theta_j) (t/\theta_j)^{\alpha_j-1}$.

Regression models. Let $\mathbf{x}$ be a vector of covariates for the unit under study. Two main approaches for regression modeling in survival analysis are *proportional hazards models* and *accelerated life models*. The versions for competing risks can be given as follows:

Proportional hazards

The subhazard functions are given by $\lambda_j(t; \mathbf{x}) = \psi_j(\mathbf{x}) \lambda_{0j}(t)$ where $\psi_j(\mathbf{x})$ is a positive function of the covariates, for example, $\psi_j(\mathbf{x}) = \exp\{\boldsymbol{\beta}' \mathbf{x}\}$ for a parameter vector $\boldsymbol{\beta}$. If $\lambda_{0j}(t) = \lambda_0(t)$ does not depend on j , then T and C are stochastically independent.

Accelerated life model

The dependence of $\mathbf{x}$ is here through factors $\phi_j(\mathbf{x})$ which accelerate time in such a manner that $F_j(t; \mathbf{x}) = F_{0j}(\phi_j(\mathbf{x})t)$.

Modeling of Latent Failure Times

The traditional way of modeling dependent risks has been through specification of the joint distribution function $K(t_1, \dots, t_k)$ or the joint survival function $\bar{K}(t_1, \dots, t_k)$. Classical examples are the bivariate normal and Weibull distributions considered by Moeschberger [19] and for which there are no identifiability problems. Other simple examples are given by the following.

Example: bivariate exponential (Gumbel [20])

Let $k = 2$ and define

$$\bar{K}(t_1, t_2) = \exp\{-\lambda_1 t_1 - \lambda_2 t_2 - \nu t_1 t_2\} \quad (13)$$

Then $\lambda_j(t) = \lambda_j + \nu t$, so that the independent risks model giving the same subdistribution functions would have marginal survival functions $\bar{G}_j^*(t) =$

$\exp\{-\lambda_j t - \nu t^2/2\}$. However, the true marginal survival functions corresponding to the given $\bar{K}(t_1, t_2)$ are $\bar{G}_j(t) = \exp\{-\lambda_j t\}$. The dilemma is that it is not possible to distinguish between these two models from observation of (T, C) . Note, however, that for both models we have identifiability of all the parameters $\lambda_1, \lambda_2, \nu$.

Example: PM modeling In the section title “Uses of Competing Risks in Reliability and Maintenance Studies” we considered the case with $k = 2$ where T_1, T_2 are, respectively, the time of critical failure of a component and the potential time of a PM. Cooke [21, 4] introduced the notion of random signs censoring which is tailored for such cases. In our notation the PM time T_2 is called a *random signs* censoring of the failure time T_1 if the event $\{T_2 < T_1\}$ is stochastically independent of T_1 . The idea is that the component emits some kind of signal before failure, and that this signal is discovered with a probability which does not depend on the age of the component. The interesting fact is that random signs censoring implies identifiability of the distribution of T_1 . Lindqvist *et al.* [22] suggested a special case of random signs censoring obtained by introducing a so-called repair alert function which describes the “alertness” of the maintenance crew as a function of time.

Statistical Inference

Consider the case where we have data of the form (T, C) for n independent observation units. In practice such data are often right censored by some source independent of the k given risks. For example, this could be a censoring due to a time limit of the experiment (type I censoring). If the i th observation is noncensored, we observe both the lifetime t_i and the cause c_i . On the other hand, if the i th observation is right censored at time t_i , then we do not observe c_i and all we know is that $T > t_i$. If we let $\delta_i = 0$ if the i th observation is censored and $\delta_i = 1$ otherwise, we get the likelihood function

$$L = \prod_{i=1}^n f_{c_i}(t_i)^{\delta_i} \bar{F}(t_i)^{1-\delta_i} = \prod_{i=1}^n \lambda_{c_i}(t_i)^{\delta_i} \bar{F}(t_i) \quad (14)$$

where the last equality follows by using equation (3). Further, defining $\delta_{ij} = I(c_i = j)$ when $\delta_i = 1$ and

$\delta_{ij} = 0$ when $\delta_i = 0$ and using equation (5), we arrive at (see Lawless [6, Chapter 9.1])

$$L = \prod_{j=1}^k \left[\prod_{i=1}^n g_j^*(t_i)^{\delta_{ij}} \bar{G}_j^*(t_i)^{1-\delta_{ij}} \right] \equiv \prod_{j=1}^k L_j \quad (15)$$

where $g_j^*(t) = \lambda_j(t) \bar{G}_j^*(t)$ is the density function corresponding to $\bar{G}_j^*(t)$.

Thus we can write L as a product of the likelihoods L_j , where L_j has the same form as the likelihood function of a censored sample associated with the j th failure cause where all observations where C is not observed to equal j are treated as censorings.

Any of the above expressions for the likelihood L may be used for parametric **maximum likelihood estimation**, depending on the way the model is defined. Equation (15) has important implications for nonparametric estimation. In fact, the likelihood L_j is of the same form as the one leading to the usual Kaplan–Meier estimator (see [10]) of a survival function under independent right censoring. This means, in particular, that the “artificial” survival functions $\bar{G}_j^*(t)$ and hence $\Lambda_j(t) = -\log \bar{G}_j^*(t)$, can be estimated nonparametrically by the Kaplan–Meier estimator. Alternatively, one may from the same reasoning estimate the Λ_j for each j using the Nelson–Aalen estimator [10]. In this case, denoting the resulting estimator by $\hat{\Lambda}_j(t)$, it follows from equation (4) that one may estimate the F_j nonparametrically by

$$\hat{F}_j(t) = \int_0^t \hat{\bar{F}}(u) d\hat{\Lambda}_j(u), \quad j = 1, \dots, k \quad (16)$$

where $\hat{\bar{F}}(t)$ is the ordinary Kaplan–Meier estimate of the survival function $\bar{F}(t)$ of T . Note that this estimator uses the censored data obtained by collapsing the k failure causes into one single cause.

Beyond Classical Competing Risks

Markov process models Aalen [23] modeled the classical competing risks problem as a continuous-time *Markov process* with one working state (“0”) and k absorbing failure states corresponding to the k risks. More generally one may consider **Markov processes** with more complex state spaces and again k absorbing states corresponding to the k failure types. This leads to the consideration of multivariate phase

type distributions, see Assaf *et al.* [24]. Hokstad and Frøvig [25] considered failure models for periodically tested items where the failures are either degraded or critical. Whitmore [26] discussed the use of first-passage-time distributions connected with multidimensional *Brownian motion* as models for competing risks.

Competing risks in repairable systems Consider a system where failures are classified in k different types. Until now we have considered the case of non-repairable units observed until failure or PM. Now assume that the unit is repaired after failure, then is put into operation again, and that the process continues in this way (see **Repairable Systems: Statistical Inference**). Suppose that, at each failure, the type of event is recorded. Assume also that time durations of repair and maintenance can be disregarded, so that the system is always restarted immediately after failure or maintenance action. This leads to the observation of a marked point process $(S_1, C_1), (S_2, C_2), \dots$ with successive failure times $0 < S_1 < S_2 < \dots$ and marks C_i in $\{1, 2, \dots, k\}$. The properties of such a process depends on the repair strategy. For example, a perfect repair (renewal) of the system at failures leads to independent and identically distributed pairs (T_i, C_i) where $T_i = S_i - S_{i-1}$ ($i = 1, 2, \dots$) and $S_0 = 0$. We are hence back to the basic case considered in this article. In general, however, the situation could be more complicated. Doyen and Gaudoin [27] present a point process approach for modeling of **imperfect repair** in competing risks situations between failure and PM. Bedford and Lindqvist [28] considered a series system of k repairable components where only the failing component is repaired at failures. A general setup for this kind of processes is suggested by Lindqvist [29].

Discussion

As argued in the article, the latent failure time approach to competing risks is particularly useful in reliability applications. However, as risks will usually be dependent, the identifiability problem occurs. Recall that although additional assumptions on the dependence may lead to identifiability, these assumptions are nontestable from data of the form (T, C) . Prentice *et al.* [30] therefore rejected the latent failure time approach and instead advocated the use of the observable subhazard functions in analyses of

competing risks. One may argue against this, however, that in practical applications it often makes good sense to use ones information and prior beliefs in order to model the underlying probability mechanisms beyond what is actually observable.

On the other hand, an erroneous assumption of independent risks may lead to seriously misleading conclusions. As noted by Cooke [3], such assumptions are often made in the assessments of competing failure rates in reliability databases. One then assumes that for each of the k failure causes, failures occur as independent *Poisson processes*. This implies, however, that the rate of occurrence of each of the competing risks would be unaffected by removing the others. For competing risks corresponding to critical failure and PM this means that the rate of occurrence of critical failures would be unaffected by stopping PM activity, an assumption which is completely unreasonable. The appropriate method would be to invoke a more careful modeling by competing risks, using if possible all available information. More sophisticated methods for analysis of competing risks in connection with repairable systems, as briefly mentioned in the previous section, may be needed here.

Subjective Life Models

Introduction

Subjective life models form a part of the decision-theoretic approach to equipment maintenance. In decision theory, the optimal maintenance policy is the policy that maximizes the decision maker's expected utility. This requires a utility function expressing the benefits and costs and a probability distribution expressing the decision maker's beliefs.

Models arise when the distribution is specified in two assessments. The first assessment is a general assumption concerning the nature of the aging process. This leads to a parametric model for the lifetimes of the items. The second assessment concerns the parameters themselves and leads to a Bayesian framework for inference.

The first five sections lay the groundwork for the models by defining **maintenance policies** that formalize the optimization procedure. It shows how the concepts of hazard and their differentials replace the classical failure rates and hazard gradients (see Barlow and Proschan [1] for the classical definitions). The remaining sections derive subjective life models from first principles and show under what conditions we can expect to obtain the classical failure models.

Lifetimes

Consider a sequence of N components with lifetimes $\mathbf{X} = X_1, \dots, X_N$ having outcomes $\mathbf{x} = x_1, \dots, x_N$. It will not be necessary to consider an infinite sequence from the outset because the distribution on this sequence is subjective and need not be estimated. To show the connections with the classical theory, we will consider limits when $N \rightarrow \infty$, but in practice there are many problems concerning even a small number of components and this is a definite advantage.

The sequence $\mathbf{X}$ is an element of $\mathbb{R}_+^N$ and so the beliefs are a subjective probability distribution P on this sample space. It is important to see that this sample space is not a Euclidean N -space. There is no metric defining distance or angles and so it immediately follows that Marshall's hazard gradient (see Marshall [2]) cannot be defined since a gradient gives the *direction* of greatest

increase and the concept of direction cannot be defined.

However, lifetime space has structure that Euclidean space does not have and this can be used to define the survival distribution and the hazard, *viz.*

$$\bar{F}(\mathbf{X}) = P(\mathbf{X} \geq \mathbf{x}) \quad \text{and} \quad H(\mathbf{X}) = -\log \bar{F}(\mathbf{X}) \quad (1)$$

Unlike coordinates in Euclidean space, items are physical entities and they endow the lifetime space with N physical coordinates at any point. Such a space is also known as a *fiber bundle*. The survival distribution is useful for a subjectivist because they depend only on the fibers and are invariant under changes of units for measuring lifetimes. It would not be useful for a subjectivist in Euclidean space since it is not invariant under its invariance group, i.e., rotations and translations.

Maintenance Policies

A maintenance policy is a path $\mu : \mathbb{R} \rightarrow \mathbb{R}_+^N$ mapping each value t of time into a sequence of ages for the items. For instance, a replace-at-failure policy would start at $\mathbf{0}$, first run to $x_1, 0, \dots, 0$, then to $x_1, x_2, 0, \dots, 0$ and so on until $x_1, \dots, x_N$. In general, the path would run from $\mathbf{0}$ (unless the items are used) in any positive direction (unless the items rejuvenate). Time is the parameter on this path. This is a very general mathematical representation and covers any type of operating policy as well.

The tangent vector to the maintenance policy at any point is the aging rate:

$$\vec{a} = \sum_{i=1}^N \dot{x}_i \frac{\partial}{\partial x_i} \quad (2)$$

Here $\partial/\partial x_i$ is the unit vector in the i direction, i.e., a unit of aging of the i th item. The aging rate specifies the rate at which each item is being used. Typically, we assume that one of the $\dot{x}_i$'s is unity and the rest zero, and so measure the lifetime of the current item in time t , but it is significant that we do not have to do this and we can accelerate the aging. Think of the aging-rate vector as an engineer or a physicist would: as arrow tangent to the path that exists independent of its coordinate representation

2 Subjective Life Models

in lifetime space $(\dot{x}_1, \dots, \dot{x}_N)$ which depends on the units with which we measure lifetime.

Hazard Differential and Failure Rate

A maintenance policy together with the hazard provides a function $H \circ \mu : \mathbb{R} \rightarrow \mathbb{R}$ that maps each value of time into a hazard. The time derivative of this composite function is the failure rate

$$r(t) = \dot{H} = \frac{d(\mu \circ H)}{dt} = \sum_{i=1}^N \dot{x}_i \frac{\partial H}{\partial x_i} \quad (3)$$

Notice that in the subjective framework, the failure rate depends on the maintenance policy and we have used Newton's fluxion notation to bear this out. If the items are used differently, the failure rate will change.

To find a differential quantity that is independent of the path, we need to consider the differential of the hazard function

$$\mathbf{h} = dH = \sum_{i=1}^N \frac{\partial H}{\partial x_i} dx_i = \sum_{i=1}^N H'_i dx_i \quad (4)$$

Here we are using Leibniz's derivative notation for the partial hazards. The hazard differential is a 1-form which we will call the hazard differential and it is the correct replacement for Marshall's hazard gradient. As a 1-form, it acts naturally on the aging vector to produce the failure rate

$$r = \mathbf{h} \cdot \vec{a} = \sum_{i=1}^N H'_i \dot{x}_i \quad (5)$$

Here $\cdot$ is the tensor saturation operator.

The failure rate of the i th item can be defined by considering an aging-rate $\vec{1}_i$ vector that is 0 on all except the $\dot{x}_i$ component:

$$r_i(t|\mathbf{x}) = \mathbf{h} \cdot \vec{1}_i = H'_i(t|\mathbf{x}) \quad (6)$$

This corresponds most closely to the notion of a failure rate in the classical theory. However, notice that the failure rate depends where on the path, i.e., at which $\mathbf{x} = \mu(t)$ the aging rate is anchored, which is emphasized here by conditioning on $\mathbf{x}$; knowing that items have survived until $\mathbf{x}$ changes the decision maker's beliefs concerning the failure rate.

Geometrically, think of the hazard as a mountain on the lifetime space. As you move along the maintenance path, you climb up the hazard mountain. Locally the mountain is approximated by the form $\mathbf{h}$ in the same way the path is approximated by the vector $\vec{a}$ and the result of a small movement is the failure rate. The hazard differential can be pictured geometrically by a set of straightened-out level lines of the hazard function. Its coordinate representation is the row $(H'_1, \dots, H'_N)^T$ consisting of the partial hazards and the failure rate can be calculated as the inner-product-like contraction of that with the coordinate representation of the aging vector as in equation (3). This inner product does not depend on the particular coordinates and the failure rate emerges as an invariant. This is also expressed by saying that the coordinate representation of the hazard differential is contravariant and that of the failure rate is covariant.

Optimal Policies

A maintenance policy maps every value of the lifetimes into a consequence that includes all the benefits and costs. The utility of such a consequence is measured by a function $U : \mathbb{R}_+^N \rightarrow \mathbb{R}$. The optimal policy is then the policy whose expected utility

$$EU = \int_{\mathbb{R}_+^N} U(\mathbf{x}) P(d\mathbf{x}) \quad (7)$$

is higher than all other available policies. The optimal policy is not necessarily unique, but the decision maker is indifferent which of the optimal policies is followed.

This optimization is easier to do incrementally. Differentiate the expression for the expected utility with respect to time to obtain the flow of expected utility at any time t :

$$\dot{EU}(t) = \int_{\mathbb{R}_+^N} \dot{U}(\mathbf{x}) r(t|\mathbf{x}) d\mathbf{x} \quad (8)$$

This expression highlights the importance of the failure rate. The expected utility flow is a weighted average of the utility flows, and the weights are represented by the failure rate.

The picture that emerges is that of gathering utility per unit of time as we move along the path of the

maintenance policy. The expected utility of the policy is found by integrating along the path μ

$$EU = \int_{\mu} \dot{E}U(t) dt \quad (9)$$

In nonsubjective approaches, concepts such as “reliability” and “availability” are used to judge maintenance policies. Here, the utility is the place to encapsulate any such requirements. The utility flow $\dot{U}$ should be formulated to reflect any benefit for uptime, cost for downtime, or any other benefits and costs associated with the operation of the equipment and purchasing and replacing the parts. If the utility flow is correctly formulated, no other requirements are needed. While the utility of uptimes and downtimes may be modeled this way, there are elements such as replacement costs that typically occur instantly, at least theoretically, and they should be added on during the integration.

Lifetime Models

In the classical theory, a parametric probability model such as the exponential or Weibull model is assumed with the parameters estimated. The first problem in applying this approach here is that the assumption of the model needs to be justified on a subjective basis, i.e., motivated from first principles so that the decision maker can corroborate that the model corresponds to his beliefs. The second problem concerns the parameters. Since the number of items is allowed to be very small, standard **estimation** procedures do not apply. Therefore, the parameters need to be defined in such a way that they relate to the finiteness of the sequence.

In the following subsections, we will describe the procedure for establishing subjective models from first principles, for several popular life models. We then show how the classical equivalents emerge as limiting cases for $N \rightarrow \infty$.

No-Aging Property and the Exponential Model

Consider a maintenance policy at time t and suppose none of the items has died, having lived until $\mathbf{x} = \mu(t)$. For the next interval $h > 0$ of operation, the decision maker can employ any of the N items. If the decision maker considers that the chances of the items dying in this interval are equal for all $\mathbf{x}$ and

h , this decision maker considers that these items do not age. Specifically, the no-aging property requires that

$$\bar{F}(x_i + h | \mathbf{X} \geq \mathbf{x}) = \bar{F}(x_j + h | \mathbf{X} \geq \mathbf{x}) \quad (10)$$

for all $h, \mathbf{x}$ and $i, j \in \{1, \dots, N\}$. The items are all the same, no matter how much they are used.

The no-aging property is a first principle from which we can derive a parametric model. Let the average lifetime be

$$\theta = \frac{1}{N} \sum_{i=1}^N x_i \quad (11)$$

Then it follows that a subsequence $X_1, \dots, X_n$ of $\mathbf{X}$ has a survival distribution that can be written as a mixture as follows:

$$\bar{F}(\mathbf{x}_n) = \int_0^\infty \left[1 - \frac{\sum_{i=1}^n x_i}{N\theta} \right]^{N-1} P(d\theta) \quad (12)$$

This is the class of Schur-constant distributions. The mixture represents a parametric model for a finite population; the parameter is a function of only the N lifetimes. The model is a Bayesian model in the sense that, if a subsequence of lifetimes has been observed, the decision maker can employ a posterior distribution for the parameter θ that is calculated using Bayes' theorem as follows

$$P(d\theta | \mathbf{x}_n) \propto \frac{1}{\theta^n} \left[1 - \frac{\sum_{i=1}^n x_i}{N\theta} \right]^{N-1-n} P(d\theta) \quad (13)$$

rather than using classical estimators.

When we require the no-aging property to hold for all N , no matter how large, the no-aging property converges to the classical memoryless property. This is perhaps best seen by letting $N \rightarrow \infty$ in the above expression for the survival distribution to obtain a mixture of independent and identically distributed (i.i.d.) exponentials:

$$\bar{F}(\mathbf{x}_n) = \int_0^\infty \prod_{i=1}^n e^{-x_i/\theta} P(d\theta) \quad (14)$$

4 Subjective Life Models

The parameter can now be interpreted as the limiting average lifetime, and Bayesian procedures can still be used to infer the posterior distribution as before, although the likelihood is now the exponential.

Notice that in the subjective approach, the finite population models are the natural models to consider. This is an advantage since oftentimes there are only a small number of items. These models are not the usual i.i.d. models since, even conditional on the average lifetime, they cannot be independent unless the number of items increases indefinitely. Also notice that the parameter θ emerges as a rigorously defined random variable, i.e., as a function on the sample space $\mathbb{R}_N^+$. This gives it an immediate physical meaning, obviates the need for a separate parameter space, and makes a Bayesian approach to inference unavoidable.

Generalized Weibull Model

The no-aging property forms the basis for a large class of models that can be characterized as generalized Weibull models. Although the no-aging property (equation 10) might not apply to the lifetimes directly, the decision maker may judge that there is some continuous increasing function ψ of the lifetimes such that the no-aging property applies to the transformed values instead. The power function

$$\psi(x_i) = x_i^\alpha \quad (15)$$

with $\alpha, \beta > 0$ is an example. In particular, when items to which the no-aging property applies are accelerated at a rate ψ^{-1} , then the no-aging property will apply to $\psi(x_i)$.

The parametric form for the distribution is easy to find:

$$\bar{F}(\mathbf{x}_n) = \int_0^\infty \left[1 - \frac{\sum_{i=1}^n \psi(x_i)}{N\theta} \right]^{N-1} P(d\theta) \quad (16)$$

where the parameter now is

$$\theta = \frac{1}{N} \sum_{i=1}^N \psi(x_i) \quad (17)$$

The limiting form is

$$\bar{F}(\mathbf{x}_n) = \int_0^\infty \prod_{i=1}^n e^{-\psi(x_i)/\theta} P(d\theta) \quad (18)$$

Substituting x_i^α for $\psi(x_i)$ gives the familiar i.i.d. Weibull model.

Notice that the parameter α , or, in general, any of the parameters describing the functional form of ψ , is different in nature from the parameter θ . This distinction does not appear in nonsubjective approaches. Here θ is a statistical parameter for which the decision maker has a probability distribution, since it is a function on the sample space, and Bayesian methods can be used to estimate it. However, α is not a function of the sample space, the decision maker has no probability distribution for it, and it makes no sense to attempt to estimate it unless we enlarge the sample space in some manner so that it can be defined as a function. Instead, α describes the acceleration of the items or some other physical law that transforms lifetimes, so that the no-aging property applies.

Aging, Schur Convexity, and Increasing Failure Rate (IFR) Models

Univariate life distributions representing aging items have been described as having increasing failure rate and the corresponding distributions as IFR. The problem with the IFR concept from a subjective point of view is that it is not preserved under mixing, i.e., if $\bar{F}(x|\theta)$ is IFR then $\bar{F}$ is not necessarily IFR and this latter survival function is what is used for decision making.

The appropriate subjective definition of aging was first given in Barlow and Mendel [3]: items are considered to exhibit the aging property if

$$\bar{F}(x_i + h|\mathbf{X} \geq \mathbf{x}) \geq \bar{F}(x_j + h|\mathbf{X} \geq \mathbf{x}) \quad (19)$$

for all $h > 0$ and $\mathbf{x}$ whenever $x_i < x_j$. The joint distribution for N items represents aging components if and only if the joint survival distribution is Schur concave. Also, any mixture of IFR distribution is Schur concave, and so Schur concavity is the appropriate generalization of the IFR property.

For the failure rate itself, we have the following. Let $x_{[1]} \leq x_{[2]} \leq \dots \leq x_{[N]}$ denote an increasing rearrangement of the lifetimes. The failure $r_{[i]}(\mathbf{x})$ rate of

the $[i]$ th component is found by saturating the hazard differential by the unit aging vector in the $[i]$ th direction. The aging property is then found to be equivalent to

$$r_{[1]} \leq r_{[2]} \leq \cdots \leq r_{[N]} \quad (20)$$

The subjectivist failure rates are indeed increasing.

Summary

The subjective approach sees lifetime modeling in the context of optimal decision making. A utility flow expresses all the benefits and costs associated with the various outcomes under a maintenance policy and the optimum policy is the one exhibiting the highest expected utility.

The expectation is taken over an unconditional joint distribution. A decision maker has to make some assessment about this distribution and this is made easier through the concepts of no-aging and aging. These concepts are generalizations of classical concepts such as the memoryless property and the IFR property.

In this way, the subjective life models provide a consistent and general framework for reliability analysis.

Stochastic Orders and Aging

Introduction

Many reliability systems or components of such systems have random lifetimes that indicate aging properties of these systems or components. Most of these aging properties can be characterized by various stochastic orders. Such characterizations are useful for the identification of the corresponding aging properties and for a better understanding of the meaning of these properties. In this article we describe such characterizations. The characterizations can be used in practice to develop various inequalities that yield bounds on various probabilistic quantities of interest. In this article “increasing” and “decreasing” stand for “nondecreasing” and “nonincreasing”, respectively. Expectations are assumed to exist whenever they are mentioned.

Some Stochastic Orders

In this section we give the definitions of some stochastic orders that will be used in the sequel. Useful references that cover the area of stochastic orders are Shaked and Shanthikumar [1] and Müller and Stoyan [2]. Let X and Y be two absolutely continuous nonnegative random variables with distribution functions F and G , survival functions $\bar{F} \equiv 1 - F$ and $\bar{G} \equiv 1 - G$, and density functions f and g . For the sake of simplicity we assume that the supports of X and Y are $(0, \infty)$. Let F^{-1} and G^{-1} denote the quantile functions of X and Y . The random variable X is said to be smaller than the random variable Y in the

- *Ordinary stochastic order* (denoted as $X \leq_{\text{st}} Y$) if $\bar{F}(x) \leq \bar{G}(x)$ for all x .
- *Hazard rate order* (denoted as $X \leq_{\text{hr}} Y$) if $\bar{F}(x)\bar{G}(y) \geq \bar{F}(y)\bar{G}(x)$ for all $x \leq y$.
- *Mean residual life order* (denoted as $X \leq_{\text{mrl}} Y$) if $\bar{G}(x) \int_x^\infty \bar{F}(y) dy \leq \bar{F}(x) \int_x^\infty \bar{G}(y) dy$ for all $x \geq 0$.
- *Harmonic mean residual life order* (denoted as $X \leq_{\text{hmrl}} Y$) if $(\int_x^\infty \bar{F}(y) dy)/EX \leq (\int_x^\infty \bar{G}(y) dy)/EY$ for all $x \geq 0$.
- *Dispersive order* (denoted as $X \leq_{\text{disp}} Y$) if $G^{-1}(\alpha) - F^{-1}(\alpha)$ is increasing in $\alpha \in (0, 1)$.

- *Excess wealth order* (denoted as $X \leq_{\text{ew}} Y$) if $\int_{F^{-1}(\alpha)}^\infty \bar{F}(x) dx \leq \int_{G^{-1}(\alpha)}^\infty \bar{G}(x) dx$ for all $\alpha \in (0, 1)$.
- *Increasing convex order* (denoted as $X \leq_{\text{icx}} Y$) if $E[\phi(X)] \leq E[\phi(Y)]$ for all increasing convex functions ϕ for which the expectations are defined.
- *Increasing concave order* (denoted as $X \leq_{\text{icv}} Y$) if $E[\phi(X)] \leq E[\phi(Y)]$ for all increasing concave functions ϕ for which the expectations are defined.
- *Dilation order* (denoted as $X \leq_{\text{dil}} Y$) if $X - EX \leq_{\text{icx}} Y - EY$.
- *Convex transform order* (denoted as $X \leq_c Y$) if $G^{-1}F(x)$ is convex in $x \geq 0$.
- *Star order* (denoted as $X \leq_* Y$) if $G^{-1}F(x)$ is starshaped in x ; that is, if $G^{-1}F(x)/x$ increases for $x \geq 0$.
- *Superadditive order* (denoted as $X \leq_{\text{su}} Y$) if $G^{-1}F(x)$ is superadditive in x ; that is, if $G^{-1}F(x+y) \geq G^{-1}F(x) + G^{-1}F(y)$ for all $x \geq 0$ and $y \geq 0$.
- *Laplace transform order* (denoted as $X \leq_{\text{Lt}} Y$) if $E[\exp\{-sX\}] \geq E[\exp\{-sY\}]$ for all $s > 0$.

Characterizations of Aging Properties

Throughout this section, X denotes a random lifetime, that is, a nonnegative random variable. For simplicity of exposition we assume that X is absolutely continuous with distribution function F , survival function $\bar{F} \equiv 1 - F$, and density function f . Unless stated otherwise, it will also be assumed that the support of X is $(0, \infty)$. For any event A , we use the notation $[X|A]$ to denote any random variable that is distributed according to the conditional distribution of X given A . The results below can be found in Shaked and Shanthikumar [1], unless stated otherwise.

Most of the characterizations in this section are based on stochastic comparisons of residual lives at different times. Another kind of characterization that we describe is based on comparison of the “aging” random variable with an exponential random variable, which in the context of reliability theory, has the “nonaging” property.

Increasing and Decreasing Failure Rate (IFR and DFR)

The random variable X is said to have the aging property of increasing failure rate (IFR) if $\bar{F}$ is

2 Stochastic Orders and Aging

logconcave. It has the property of decreasing failure rate (DFR) if $\bar{F}$ is logconvex. The ordinary stochastic order can be used to characterize the IFR and DFR notions as follows.

Theorem 1 *The random variable X is IFR [DFR] if, and only if, $[X - t | X > t] \geq_{st} [\leq_{st}] [X - t' | X > t']$ whenever $t \leq t'$.*

The hazard rate order can be used to characterize the IFR and DFR notions as follows.

Theorem 2 *The random variable X is IFR [DFR] if, and only if, one of the following equivalent conditions holds (when the support of X is bounded, condition 3 does not have a simple DFR analog):*

1. $[X - t | X > t] \geq_{hr} [\leq_{hr}] [X - t' | X > t']$ whenever $t \leq t'$.
2. $X \geq_{hr} [\leq_{hr}] [X - t | X > t]$ for all $t \geq 0$.
3. $X + t \leq_{hr} X + t'$ whenever $t \leq t'$.

Similarly, the dispersive order can characterize the IFR and DFR notions as follows (see Belzunce *et al.* [3] and Pellerey and Shaked [4]).

Theorem 3 *The random variable X is IFR [DFR] if, and only if, one of the following equivalent conditions holds:*

1. $[X - t | X > t] \geq_{disp} [\leq_{disp}] [X - t' | X > t']$ whenever $t \leq t'$.
2. $X \geq_{disp} [\leq_{disp}] [X - t | X > t]$ for all $t \geq 0$.

Another characterization of the IFR and DFR notions, given in Belzunce *et al.* [5], is the following.

Theorem 4 *The random variable X is IFR [DFR] if, and only if, $[X - t | X > t] \geq_{icv} [\leq_{icv}] [X - t' | X > t']$ whenever $t \leq t'$.*

In some places in the literature, if the condition of Theorem 4 holds, that is, if $[X - t | X > t] \geq_{icv} [\leq_{icv}] [X - t' | X > t']$ whenever $t \leq t'$, then X is said to have the property of IFR [DFR] in the second order stochastic dominance (IFR(2) [DFR(2)]). Theorem 4 shows that the IFR(2) [DFR(2)] property is equivalent to the IFR [DFR] property.

Still another characterization, similar to the characterizations in Theorems 1–4, is given in the next theorem (see Belzunce *et al.* [6]).

Theorem 5 *The random variable X is IFR if, and only if, $[X - t | X > t] \geq_{Lt} [X - t' | X > t']$ whenever $t \leq t'$.*

The convex transform order characterizes the IFR notion as follows. We denote any exponential random variable by Exp (no matter what the mean is).

Theorem 6 *The random variable X is IFR if, and only if, $X \leq_c \text{Exp}$.*

Increasing Failure Rate Average (IFRA)

The random variable X is said to have the aging property of increasing failure rate average (IFRA) if $-\log \bar{F}$ is starshaped; that is, if $-\log \bar{F}(t)/t$ is increasing in $t \geq 0$. The star order can be used to characterize the IFRA notion as follows. As in Theorem 6, Exp denotes any exponential random variable.

Theorem 7 *The random variable X is IFRA if, and only if, $X \leq_* \text{Exp}$.*

New Better (Worse) than Used (NBU and NWU)

The random variable X is said to have the aging property of new better than used (NBU) if $\bar{F}(s)\bar{F}(t) \geq \bar{F}(s+t)$ for all $s \geq 0$ and $t \geq 0$. It has the property of new worse than used (NWU) if $\bar{F}(s)\bar{F}(t) \leq \bar{F}(s+t)$ for all $s \geq 0$ and $t \geq 0$. The ordinary stochastic order can be used to characterize the NBU and NWU notions as follows.

Theorem 8 *The random variable X is NBU [NWU] if, and only if, $X \geq_{st} [\leq_{st}] [X - t | X > t]$ for all $t > 0$.*

Similar to Theorems 6 and 7, the superadditive order can be used to characterize the NBU notion as follows.

Theorem 9 *The random variable X is NBU if, and only if, $X \leq_{su} \text{Exp}$.*

The order $\leq_{icx}$ was used in Cao and Wang [7] to define the property of new better than used in convex order (NBUC) as follows. The random variable X is said to have the aging property of NBUC if $X \geq_{icx} [X - t | X > t]$ for all $t > 0$. The order $\leq_{icv}$ was used in Deshpande *et al.* [8] to define the property of NBU in second degree stochastic dominance (NBU(2)) as follows. The random variable X is said to have the

aging property of NBU(2) if $X \geq_{\text{icv}} [X - t | X > t]$ for all $t > 0$.

Decreasing and Increasing Mean Residual Life (DMRL and IMRL)

The nonnegative random variable X with finite positive mean is said to have the aging property of decreasing mean residual life (DMRL) if $E[X - t | X > t]$ is decreasing for $t \geq 0$. It has the property of increasing mean residual life (IMRL) if $E[X - t | X > t]$ is increasing for $t \geq 0$. The mean residual life order can be used to characterize the DMRL notion as follows.

Theorem 10 *The random variable X is DMRL if, and only if, one of the following equivalent conditions holds:*

1. $[X - t | X > t] \geq_{\text{mrl}} [X - t' | X > t']$ whenever $t \leq t'$.
2. $X \geq_{\text{mrl}} [X - t | X > t]$ for all $t \geq 0$.
3. $X + t \leq_{\text{mrl}} X + t'$ whenever $t \leq t'$.

In a similar manner the order $\leq_{\text{hmrl}}$ can be used to characterize the DMRL notion.

Theorem 11 *The random variable X is DMRL if, and only if, $[X - t | X > t] \geq_{\text{hmrl}} [X - t' | X > t']$ whenever $t \leq t'$.*

Cao and Wang [7] observed that the order $\leq_{\text{icx}}$ can be used to characterize the DMRL and IMRL notions.

Theorem 12 *The random variable X is DMRL [IMRL] if, and only if, $[X - t | X > t] \geq_{\text{icx}} [\leq_{\text{icx}}] [X - t' | X > t']$ whenever $t \leq t'$.*

Belzunce *et al.* [3] similarly observed that the dilation order can be used to characterize these **aging notions**. The result below follows from their Theorem 4 and the fact that the dilation order is location invariant.

Theorem 13 *The random variable X is DMRL [IMRL] if, and only if, $[X - t | X > t] \geq_{\text{dil}} [\leq_{\text{dil}}] [X - t' | X > t']$ whenever $t \leq t'$.*

Belzunce [9] noticed that the excess wealth order can also be used to characterize the DMRL and IMRL notions.

Theorem 14 *Let X be a continuous random variable with support $(0, \infty)$. Then X is DMRL [IMRL] if, and only if, any one of the following equivalent conditions holds:*

1. $[X - t | X > t] \geq_{\text{ew}} [\leq_{\text{ew}}] [X - t' | X > t']$ whenever $t' \geq t \geq 0$.
2. $X \geq_{\text{ew}} [\leq_{\text{ew}}] [X - t | X > t]$ for all $t \geq 0$.

There exist analogs of Theorems 6, 7, and 9 for the DMRL aging notion. According to Kocher and Wiens [10] the random variable X is said to be *smaller than Y in the DMRL order* (denoted by $X \leq_{\text{dmrl}} Y$) if

$$\frac{\int_{G^{-1}(\alpha)}^{\infty} \bar{G}(x) dx}{\int_{F^{-1}(\alpha)}^{\infty} \bar{F}(x) dx} \text{ is increasing for } \alpha \in [0, 1]$$

Theorem 15 *The random variable X is DMRL if, and only if, $X \leq_{\text{dmrl}} \text{Exp}$.*

Li and Li [11] introduced another order, denoted by $\leq_{\text{drlc}}$, such that X is DMRL if, and only if, $X \leq_{\text{drlc}} \text{Exp}$.

New Better (Worse) than Used in Expectation (NBUE and NWUE)

The nonnegative random variable X with finite mean is said to have the aging property of new better than used in expectation (NBUE) if $E[X] \geq E[X - t | X > t]$ for all $t \geq 0$. It has the property of new worse than used in expectation (NWUE) if $E[X] \leq E[X - t | X > t]$ for all $t \geq 0$. Lefèvre and Utev [12] proved that the harmonic mean residual life order can be used to characterize the NBUE notion as follows.

Theorem 16 *Let X be a nonnegative random variable with positive mean. Then X is NBUE if, and only if, any one of the following equivalent conditions holds:*

1. $X \leq_{\text{hmrl}} X + Y$ for any nonnegative random variable Y with a finite positive mean, which is independent of X .
2. $X + Y_1 \leq_{\text{hmrl}} X + Y_2$ whenever Y_1 and Y_2 are almost surely positive random variables with finite means, which are independent of X , such that $Y_1 \leq_{\text{hmrl}} Y_2$.

There exist analogs of Theorems 6, 7, 9, and 15 for the NBUE aging notion. According to Kochar and Wiens [10] the random variable X is said to be *smaller than Y in the NBUE order* (denoted by $X \leq_{\text{nbue}} Y$) if

$$\frac{1}{EX} \int_{F^{-1}(\alpha)}^{\infty} \bar{F}(x) dx \leq \frac{1}{EY} \int_{G^{-1}(\alpha)}^{\infty} \bar{G}(x) dx$$

for all $\alpha \in [0, 1]$

Theorem 17 *The random variable X is NBUE if, and only if, $X \leq_{\text{nbue}} \text{Exp}$.*

Note that for any two nonnegative random variables Z and W with positive expectations we have $Z \leq_{\text{nbue}} W \iff (Z/EX) \leq_{\text{ew}} (W/EX)$. Thus, Theorem 17 can be rewritten as follows.

Theorem 18 *The random variable X is NBUE if, and only if, $(X/EX) \leq_{\text{ew}} \text{Exp}(1)$, where $\text{Exp}(1)$ denotes an exponential random variable with mean 1.*

An aging notion that is closely related to the NBUE notion is the notion of the harmonic new better than used in expectation (HNBUE). Formally, the random variable X with mean $\mu > 0$ is said to have the aging property of HNBUE if $X \leq_{\text{icx}} \text{Exp}(\mu)$, where $\text{Exp}(\mu)$ denotes an exponential random variable with mean μ . The random variable X with mean $\mu > 0$ is said to have the property of harmonic new worse than used in expectation (HNWUE) if $X \geq_{\text{icx}} \text{Exp}(\mu)$. Note that by known basic properties of the orders $\leq_{\text{icx}}$ and $\leq_{\text{dil}}$ it follows that the random variable X with mean $\mu > 0$ is HNBUE [HNWUE] if, and only if, $X \leq_{\text{dil}} [\geq_{\text{dil}}] \text{Exp}(\mu)$. The harmonic mean residual life order can be used to characterize the HNBUE and HNWUE notions as follows.

Theorem 19 *The random variable X with mean $\mu > 0$ is HNBUE [HNWUE] if, and only if, $X \leq_{\text{hmrl}} [\geq_{\text{hmrl}}] \text{Exp}(\mu)$.*

Characterization in Reliability

What is the Problem of Characterization of Probability Distributions?

The problem of characterization of distributions is today a section of **probability theory** and mathematical statistics that is rather substantial in its size and variety of accumulated facts. The aim of characterization theory is to describe a class of all probability distributions possessing some desirable property $\mathcal{P}$. The property $\mathcal{P}$ is usually the main property we would like to use for the construction of mathematical models of real world phenomenon. Characterization theorems utilize numerous classical tools of mathematical analysis, such as, advanced theory of functions of complex variables, differential equations of different types, theory of functional equations, and other tools. It is clear that $\mathcal{P}$ may be connected, say, with the property of **aging**, and therefore the connection between characterization theory and reliability is obvious. It is possible to have classification of corresponding problems of reliability theory based on the types of property $\mathcal{P}$ in use or the analytical tools utilized to obtain the solution. Both methods are popular among the specialists.

Characterizations Connected to the Lack of Memory Property

A considerable amount of results dealing with characterization of exponential distribution, the Weibull distribution, and some other laws either have their origin in mathematical theory of reliability or can be interpreted in terms of this theory. Some of them are of certain practical interest, while others have only a theoretical importance. However, all these results are important since they give an idea of a mechanism of appearance of distributions either in problems associated with the aging of technical devices or in connection with various methods of control of these devices (e.g., with verification or durability). One of the best analyzed characterizations of this kind is the exponential distribution by the lack of memory property, or, in other words, by the lack of aging property.

Lack of memory (aging) property is defined by the following. Let T be a positive continuous random variable (rv) having interpretation as the lifetime of a device. The probability of having a failure in time interval $(t, t + \Delta t]$ given that there was no failure on time interval $(0, T]$ is

$$\mathbb{P}\{t < T \leq t + \Delta t | T > t\} = \frac{\mathbb{P}\{t < T \leq t + \Delta t\}}{\mathbb{P}\{T > t\}} \quad (1)$$

On the other hand, for a new device of the same type, the probability of having a failure in a time interval of the same length Δt but starting from zero that is, in the interval $(0, \Delta t)$ is $\mathbb{P}\{0 < T \leq \Delta t\}$. If there is no aging for the device, the probabilities have to be identical:

$$\frac{\mathbb{P}\{t < T \leq t + \Delta t\}}{\mathbb{P}\{T > t\}} = \mathbb{P}\{0 < T \leq \Delta t\} \quad (2)$$

for all $t > 0, \Delta t > 0$. This relation can be expressed in terms of a survival function (sf) $S(x) = \mathbb{P}\{T > x\}$, and coincides with the well-known Cauchy functional equation for exponential function [1]. It means *the lack of aging property is valued for the exponential distribution with arbitrary scale parameter and only for it*. An equivalent form of the lack of aging property is

$$\mathbb{P}\{T > t + x | T > t\} = \mathbb{P}\{T > x\} \quad (3)$$

A detailed study of the lack of memory property and its generalizations can be found in [2].

One of the most interesting generalizations of the lack of aging property is the *integrated (or averaged) lack of memory property*. This represents the case when x in equation (3) is a value of rv independent of T . One of typical formulations of the averaged lack of memory property is the following:

Let $\{X_t, t > 0\}$ be a family of rv with an sf $H_t(x)$ and T be a positive rv with sf $S(t)$. Suppose that $\min\{x \in \text{supp} H_t\} > t$. Then the averaged lack of memory property is defined by the relation

$$\mathbb{P}\{T > X_t | T > t\} = \mathbb{P}\{T > X_t - t\} \quad (4)$$

Under some additional conditions, the averaged lack of memory property is equivalent to the exponentiality of rv T . The averaged lack of memory property can be analytically reformulated as a convolution-type equation. Either the method of

2 Characterization in Reliability

intensively monotone operators [3] or the Choquet–Deny theorem [4] is used for the solution.

The aforementioned methods are applicable to another type of generalization of the lack of memory property. Namely, let h be a real-valued continuous function. Consider the condition of *constancy of conditional expected values*:

$$\mathbb{E}(h(T - z) | T > z) = \mathbb{E}(h(T)) \quad (5)$$

Under some restriction imposed on the function h this property is characteristic of exponential distribution. The method based on Choquet–Deny theorem [4] is applicable to the case of a monotone h function, while the method of intensively monotone operators [3] can be applied to nonmonotone h . There exist some examples, showing that the characterization is not true for some continuous nonmonotonic h [5].

Functioning of Redundant Systems

The *relevation-type equation* appeared in reliability theory in the following way. Let there be two types of elements working simultaneously. The first element is the servicing one and the second is an element in storage. If an element of the first type fails, then its role is fulfilled by a survival in storage (moreover, it is assumed that the distribution of failures of the element of the second type does not change). The failure of the device occurs after the failure of an element of the second type which has replaced the first one [6]. If the sf of the first (second) element is $S_1(t)$ ($S_2(t)$) then the sf of the system is $S_1(t) - S_2(t) \int_0^t dS_1(x)/S_2(x)$. This expression is called the *relevation of S_1 and S_2* . If an element of the second type would not work before the failure of a servicing element, then the sf of the device would be found with the help of a convolution of S_1 and S_2 that is, it would have the form of $S_1(t) - \int_0^t S_2(t - x) dS_1(x)$. Intuitively the coincidence of the relevation and the convolution of corresponding sf's signifies the lack of aging of an element of the second type. Really, under some mild conditions, the equation

$$\begin{aligned} S_1(t) - S_2(t) \int_0^t \frac{dS_1(x)}{S_2(x)} \\ = S_1(t) - \int_0^t S_2(t - x) dS_1(x) \end{aligned} \quad (6)$$

has only exponential solution for S_2 for any given S_1 [3].

Characterization of the sf's by a connection between the reliabilities of two systems

Consider technical systems $\mathcal{A}$ and $\mathcal{B}$, consisting of identical and mutually independent (from the point of failure probabilities) elements. The system $\mathcal{A}$ consists of n elements and the system $\mathcal{B}$ consists of k elements, $n > k \geq 1$. Assume that each system goes out of service under failure of at least one of its elements. If the time in service up to the failure of each element is distributed according to a nondegenerate law $F(t)$, which is continuous and strictly monotone for $t > 0$, then at any given moment of time $t > 0$ the reliability of the element is equal to $S(t) = 1 - F(t)$. Hence the reliability of the system $\mathcal{A}$ is equal to $h_1(t) = (S(t))^n$, and for the system $\mathcal{B}$ is equal to $h_2(t) = (S(t))^k$. Connect with each moment of time $t > 0$ a smallest moment $T(t) = T(t; F)$ such that the reliability of the system $\mathcal{A}$ at the moment t is equal to the reliability of the system $\mathcal{B}$ at the moment $T(t)$. It appears that the assignment of the function $T(t)$ characterizes the distribution F . It implies, for instance, the following fact. Let $b > 1$ be a constant. Assume that the limit $\lim_{t \rightarrow 0} S(t)/t^\alpha$ exists for $\alpha = \log(n/k)/\log b$. The equality $T(t; F) = bt$ holds for all $t > 0$ if and only if $F(t)$ is a distribution function of the Weibull law that is, $F(t) = 1 - \exp(-at^\alpha)$ for $t > 0$.

Among the distributions with nondecreasing hazard rate the function $T(t)$ takes maximal possible value at each moment t for exponential distribution.

The result of characterization of the Weibull distribution generalizes the following fact. Let $T_1, \dots, T_n$ be a sequence of independent identically distributed (i.i.d.) positive rv's with cumulative distribution function (cdf) F , and $T_{\min} = \min(T_1, \dots, T_n)$, $n > 2$. Suppose that for some $\alpha > 0$ there exists a positive limit $\lim_{t \rightarrow 0} (1 - F(t)/t^\alpha)$. Then T_1 and $n^{1/\alpha} T_{\min}$ are identically distributed if and only if F is the Weibull distribution. The existence of the limit above can be replaced by the fact of identical distribution of T_1 and $n^{1/\alpha} T_{\min}$ for two values of n with irrational ratio of their logarithms. Some generalizations for the case of non-i.i.d. can be founded in [3], where some generalizations for the case of random n for the characterization of the Pareto distribution are also given.

On the Reliability of Hierarchical Structures

Let $N = N_1$ be an arbitrary network called the *first generation*. The second generation N_2 is obtained from N_1 by replacing each component of N_1 by N . Similarly, if we replace each component of N_2 by N , then we get the third generation N_3 , and so on. Suppose that the components of N function independently and each component has the same probability p of proper functioning, then the chance that N functions properly is a polynomial of p , called the *reliability polynomial*, and will be denoted by $h(p)$ [7]. The n th function iteration of h is the reliability polynomial of N_n . Denote this n th iteration of h by $h^{(n)}(p)$. The theory of iterative functions is a good tool to study these hierarchical networks. The limiting distribution $\bar{F}$ of the sf's $\bar{F}_n$ of N_n with linear normalization (as n tends to infinity) can be reduced to the solution of the equation

$$\bar{F}(t) = h(\bar{F}(\tau t)) \quad (7)$$

for some $\tau \in (0, 1)$. This equation is equivalent to the property of identical distribution of T_1 and the maximum of a random number (having the probability generating function h) of i.i.d. moments $T_1, T_2, \dots$ taking in random number with probability generating function h . The description of all possible F can be given in terms of solution of Poincare equation, and depends on the number of fixed points for iterations of the function h (see [8]).

Characterizations in Special Classes of Distributions

Let T be a positive rv having sf $S(t)$. Remember that S is *NABU* (new better than used in average) if $\int_t^\infty S(x) dx \leq \mu_1 S(t)$, where $\mu_1 = \mathbb{E}(T)$. Denote $S_0(t) = S(t)$ and introduce $S_j = (j\mu_{j-1}/\mu_j) \int_t^\infty S_{j-1}(x) dx$, $\mu_j = \mathbb{E}(T^j)$. If S is *NABU* then $\mu_j \leq j!\mu_1^j$ with the equality sign if and only if S is an sf of the exponential distribution. The stability of this characterization can be expressed in the following way. Let S be an sf having the moments μ_j , $j = 1, \dots, k-1$. For any $1 \leq j \leq k$ the following holds

$$\sup_{t \geq 0} |S_j(t) - \exp\left(\frac{-t}{\mu_1}\right)| \leq 1 - \frac{\mu_{j+1}}{((j+1)\mu_1\mu_j)} \quad (8)$$

There are numerous publications on the use of characterizations for statistical test. One of such test belongs to Koul [9]. The Bahadur efficiency of this test was studied by Tchirina [10], who calculated the asymptotic of the large deviations for the test statistic, and found the class of alternatives for which the test is efficient.

Random Evolutions toward Applications

Introduction

Random evolution or stochastic evolution were introduced by Griego and Hersh [1]. They observed that certain abstract Cauchy problems are related to generators of **Markov processes**. The name of *Random evolution* is due to P. Lax. (see [2]).

An evolutionary system that changes its mode of evolution following a stochastic mode is a random evolution. For example, a particle moving on the real line with constant velocity, say V , changes it at a random time, given by the arrival of a **Poisson process** to $-V$, that is, the velocity of the particle at time t is $(-1)^{N(t)}V$, where $N(t), t \geq 0$, is a (homogeneous) Poisson process on $[0, \infty)$.

Random evolutions are models to study stochastic systems in random media (environment). In the above example, the Poisson process represent the random medium.

From a mathematical point of view, random evolutions are operator-valued stochastic processes in a Banach space. They represent an abstract form of stochastic evolutionary systems in random media. Discrete-time random evolution studied in connection with Markov chains (see [3]), and as embedded random evolution in continuous-time semi-Markov process (see [4, 5]). In Skorokhod *et al.* [6] several random evolution problems are studied.

Applications of random evolutions include population dynamics in **random environment** [7, 8]; in insurance [9]; reliability analysis [5] and so on.

In this paper we present random evolutions *via* dynamical systems, the so-called piecewise deterministic Markov processes (see [10]) in ergodic and nonergodic media.

In the next section a particular dynamical system in Markov media and its abstract model in terms of random evolutions is presented. In the section on “Asymptotic Results” two types of limit theorems for Markov random evolution are presented. Finally, in the “Concluding Remarks”, some remarks on the literature and further topics connected to random evolution are presented.

Evolutionary Systems in Markov Random Medium

Let us consider the dynamical system

$$\begin{cases} \frac{d}{dt}U(t) &= C(U(t); x(t)), \quad t \geq 0 \\ U(0) &= u \end{cases} \quad (1)$$

where the process $x(t), t \geq 0$, is a Markov process with state space E , and generator $\mathbf{Q}$, and $U(t) \in \mathbf{R}^d$. This system usually describes dynamic reliability where the Markov process $x(t), t \geq 0$, describes the structure of the system and the process $U(t)$ the physical throughput in the system, for example, temperature, pressure, velocity, and so on (see [11]).

The coupled stochastic process $(U(t), x(t)), t \geq 0$, is a Markov process, with state space $\mathbf{R}^d \times E$ and generator $\mathbf{L}$:

$$\mathbf{L}\varphi(u, x) = \mathbf{\Gamma}(x)\varphi(u, \cdot) + \mathbf{Q}\varphi(\cdot, x) \quad (2)$$

where the operator $\mathbf{\Gamma}(x)$ acts on functions $\varphi(u) \in C^1(\mathbf{R}^d)$ as follows

$$\mathbf{\Gamma}(x)\varphi(u) = C(u; x) \left(\frac{\partial}{\partial u_1}, \dots, \frac{\partial}{\partial u_d} \right) \varphi(u_1, \dots, u_d) \quad (3)$$

For example, in a two-state Markov process, $x(t)$, say $E = \{0, 1\}$ and $d = 1$, the generator $\mathbf{L}$ can be written in the following matrix form

$$\mathbf{L} = \begin{pmatrix} C_0(u) \frac{\partial}{\partial u} & 0 \\ 0 & C_1(u) \frac{\partial}{\partial u} \end{pmatrix} + \begin{pmatrix} -\lambda & \lambda \\ \mu & -\mu \end{pmatrix} \quad (4)$$

where $C_x(u) := C(u; x), x = 0, 1$.

As the trajectory of $U(t)$ at time $t + s$, with initial value $U(0) = u$, is an extension of the trajectory at time s of the trajectory with initial value $U(t; u, x)$ it is easy to see that the solution of equation (1) for fixed state $x \in E$, verifies the semigroup property

$$U(t + s; u, x) = U(s; U(t; u, x), x) \quad (5)$$

where $U(t; u, x)$ is the value of $U(t)$ on $\{U(0) = u, x(0) = x\}$.

2 Random Evolutions toward Applications

An abstract formulation of the above property can be represented by the following continuous Markov random evolution

$$\Phi(t)\varphi(u, x(t)) := \varphi(U(t); x(t)) \quad (6)$$

with the family of semigroups

$$\Gamma_x(t)\varphi(u) := \varphi(U(t; u, x)), \quad x \in E, t \geq 0 \quad (7)$$

and generators

$$\Gamma(x)\varphi(u) := C(u, x) \frac{d}{du} \varphi(u), \quad x \in E \quad (8)$$

Asymptotic Results

Let us consider the dynamical system in equation (1) in two different series schemes. The first one is the ergodic case for the switching process $x(t), t \geq 0$, and in the second one a split with absorption is considered. In both cases, average diffusion approximation limit theorems will be presented.

Let us consider the switching jump Markov processes $x^\varepsilon(t), t \geq 0, \varepsilon > 0$, in series scheme with series parameter $\varepsilon > 0$ ($\varepsilon \rightarrow 0$), with state space $(E, \mathcal{E})$, where E is a Polish space and $\mathcal{E}$ its Borel σ -algebra, and generators

$$Q^\varepsilon \varphi(x) = q(x) \int_E P^\varepsilon(x, dy) [\varphi(y) - \varphi(x)] \quad (9)$$

where $P^\varepsilon(x, dy)$ is the transition kernel of the embedded Markov chain $x_n^\varepsilon = x^\varepsilon(\tau_n^\varepsilon)$ and τ_n^ε are the jump times of $x^\varepsilon(t), t \geq 0$. The function $q(x)$ is the intensity of jumps.

Ergodic Case

Let us first present the result on averaging. The following assumptions are needed.

A1. The switching Markov process $x(t), t \geq 0$, is uniformly ergodic with stationary probability measure $\pi(B), B \in \mathcal{E}$.

A2. The function $C(u; x)$ is globally Lipschitz continuous on $u \in \mathbf{R}^d$ with common constant L for all $x \in E$. So, the system

$$\frac{d}{dt} U_x(t) = C(U_x(t); x) \quad (10)$$

has a global solution.

Theorem 1 [Average approximation] Under Assumptions A1 and A2, the solution $U^\varepsilon(t)$ of the following system

$$\begin{cases} \frac{d}{dt} U^\varepsilon(t) = C(U^\varepsilon(t); x(t/\varepsilon)) \\ U^\varepsilon(0) = u \end{cases} \quad (11)$$

converges weakly to the solution of the average equation

$$\begin{cases} \frac{d}{dt} \widehat{U}(t) = \widehat{C}(\widehat{U}(t)) \\ \widehat{U}(0) = u \end{cases} \quad (12)$$

It is worth noticing that this is a deterministic system and this averaging scheme is the so-called Bugolyubov principle.

For the *diffusion approximation* we consider the following time-scaling of the switching process.

$$\begin{cases} \frac{d}{dt} U^\varepsilon(t) = C^\varepsilon(U^\varepsilon(t); x(t/\varepsilon^2)) \\ U^\varepsilon(0) = u \end{cases} \quad (13)$$

where $C^\varepsilon(u; x) := \varepsilon^{-1} C(u; x) + C_1(u; x)$.

We suppose here that the following balance condition is fulfilled

$$\widehat{C}(u) := \int_E \pi(dx) C(u; x) = 0 \quad (14)$$

Theorem 2 [Diffusion approximation] Under Assumption A1, and the balance condition (14), the solution of the system (13) converges to a diffusion process, provided that the diffusion coefficient B is > 0 , the limit diffusion process is defined by the following infinitesimal generator

$$\mathbf{L}\varphi(u) = \widehat{C}_u \varphi'(u) + \frac{1}{2} B(u) \varphi''(u) \quad (15)$$

where the drift coefficient is

$$\widehat{C}_u = \int_E \pi(dx) [C_1(u; x) + C(u; x) R_0 C'_u(u; x)] \quad (16)$$

and the diffusion coefficient is

$$B(u) = 2 \int_E \pi(dx) C_0(u; x) R_0 C(u; x) \quad (17)$$

Operator R_0 is the potential operator of Q , that is

$$QR_0 = R_0Q = \Pi - I \quad (18)$$

and Π is the projector operator defined by $\Pi(x, dy) = \pi(dy)$, for every $x \in E$.

Notation φ', φ'' stand for the first and second derivative of function φ , and $C'_u(u; x)$ stands for the partial derivative of $C(u; x)$ with respect to the variable u .

Nonergodic Case

While the ergodic case is more adapted to availability modeling, the nonergodic case, presented here, is more adapted to reliability modeling.

Let us now consider the following split to the state space of the Markov switching processes $x^\varepsilon(t)$, $t \geq 0$, $\varepsilon > 0$,

$$E^0 = E \cup \{0\}, \quad E = \bigcup_{k=1}^N E_k, \quad E_k \cap E_{k'} = \emptyset, \quad k \neq k' \quad (19)$$

with absorbing state $\{0\}$. An interpretation of this split in reliability problems is that $E_1, \dots, E_N$ are subsets of different performance levels and 0 is the failure state of the system.

Let us suppose that the transition kernel P^ε has the following representation

$$P^\varepsilon(x, B) = P(x, B) + \varepsilon P_1(x, B) \quad (20)$$

where $P(x, B)$ is a transition kernel, coordinated with the above split (19) as follows

$$P(x, E_k) = \mathbf{1}_k(x) := \begin{cases} 1, & x \in E_k \\ 0, & x \notin E_k \end{cases} \quad (21)$$

and $P_1(x, B)$ a perturbing kernel.

The Markov supporting process $x(t)$, $t \geq 0$, on the state space $(E, \mathcal{E})$, determined by the generator

$$Q\varphi(x) = q(x) \int_E P(x, dy) [\varphi(y) - \varphi(x)] \quad (22)$$

is supposed to be uniformly ergodic in every class E_k , $1 \leq k \leq N$, with the stationary distribution $\pi_k(dx)$, $1 \leq k \leq N$, satisfying the following relations

$$\pi_k(dx)q(x) = q_k\rho_k(dx), \quad q_k = \int_{E_k} \pi_k(dx)q(x) \quad (23)$$

$$\rho_k(B) = \int_{E_k} \rho_k(dx)P(x, B), \quad \rho_k(E_k) = 1 \quad (24)$$

where ρ_k is the stationary probability of the embedded Markov chain $x_n, n \geq 0$, of the supporting Markov process $x(t)$, $t \geq 0$, on the class E_k , $1 \leq k \leq N$.

Let v be the merging function, defined by

$$v(x) = k \quad \text{if } x \in E_k, \quad 1 \leq k \leq N \quad (25)$$

Then we have

$$v\left(x^\varepsilon\left(\frac{t}{\varepsilon}\right)\right) \Longrightarrow \widehat{x}(t), \quad \varepsilon \rightarrow 0 \quad (26)$$

$\Longrightarrow$ stands for weak convergence of probability measures.

The process $\widehat{x}(t)$, $t \geq 0$ is a Markov process on the state space $E^0 = E \cup \{0\}$, with $\widehat{E} = \{1, \dots, N\}$.

The random variable ζ^ε is the absorption time or lifetime or failure time for the system, and is defined by

$$\zeta^\varepsilon := \inf \left\{ t \geq 0 : x^\varepsilon\left(\frac{t}{\varepsilon}\right) = 0 \right\} \quad (27)$$

We have $\zeta^\varepsilon \Longrightarrow \widehat{\zeta}$, as $\varepsilon \rightarrow 0$, where $\widehat{\zeta}$ is the absorption time of the merged process $\widehat{x}(t)$.

Theorem 3 [Average approximation with split and merging] Under the above assumptions the stochastic system $U^\varepsilon(t)$, $t \geq 0$, defined by

$$\begin{cases} \frac{d}{dt} U^\varepsilon(t) &= C(U^\varepsilon(t); x^\varepsilon(t/\varepsilon)) \\ U^\varepsilon(0) &= u \end{cases} \quad (28)$$

converges weakly to the averaged stochastic system $\widehat{U}(t \wedge \widehat{\zeta})$:

$$U^\varepsilon(t \wedge \zeta^\varepsilon) \Longrightarrow \widehat{U}(t \wedge \widehat{\zeta}), \quad \text{as } \varepsilon \rightarrow 0 \quad (29)$$

The limit process $\widehat{U}(t)$, $t \geq 0$, is defined by a solution of the evolutionary equation

$$\frac{d}{dt} \widehat{U}(t) = \widehat{C}(\widehat{U}(t); \widehat{x}(t)), \quad \widehat{U}(0) = 0 \quad (30)$$

on the time interval $0 \leq t \leq \widehat{\zeta}$, ($\widehat{\zeta}$ is the stoppage time of the merged Markov process $\widehat{x}(t)$, $t \geq 0$).

The averaged velocity is determined by

$$\begin{aligned}\widehat{C}(u; k) &= \int_{E_k} \pi_k(dx) C(u; x), \quad 1 \leq k \leq N, \\ \widehat{C}(u; 0) &= 0\end{aligned}\quad (31)$$

For the diffusion approximation scheme, we suppose that $N = 1$ for simplicity, and that the transition kernel has the following representation

$$P^\varepsilon(x, B) = P(x, B) + \varepsilon^2 P_1(x, B) \quad (32)$$

The random variable $\widehat{\xi}$ is exponentially distributed with parameter $\widehat{\Lambda} = pq$, where $p := -\int_E \rho(dx) P_1(x, E)$ and $q := \int_E \rho(dx)/q(x)$.

The considered system here is in the following time-scaling scheme.

$$\begin{cases} \frac{d}{dt} U^\varepsilon(t) &= C^\varepsilon(U^\varepsilon(t); x^\varepsilon(t/\varepsilon^2)) \\ U^\varepsilon(0) &= u \end{cases} \quad (33)$$

where $C^\varepsilon(u; x) := \varepsilon^{-1} C(u; x) + C_1(u; x)$.

Theorem 4 [Diffusion approximation with split and merging] Under the balance condition (14), the stochastic system (33) converges weakly, as $\varepsilon \rightarrow 0$,

$$U^\varepsilon(t \wedge \xi^\varepsilon) \Longrightarrow \xi(t \wedge \widehat{\xi}) \text{ as } \varepsilon \rightarrow 0 \quad (34)$$

The limit diffusion process $\xi(t)$, $t \geq 0$, is defined by the generator

$$\mathbf{L}\varphi(u) = b(u)\varphi'(u) + \frac{1}{2}B(u)\varphi''(u) - \widehat{\Lambda}\varphi(u) \quad (35)$$

The drift coefficient is defined by

$$b(u) = \int_E \pi(dx) [C_1(u; x) + C(u; x) R_0 C'_u(u; x)] \quad (36)$$

The **covariance** function is defined by

$$B(u) = 2 \int_E \pi(dx) C(u; x) R_0 C(u; x) \quad (37)$$

The parameter $\widehat{\Lambda}$ in (35) is the parameter of the exponential distribution of the lifetime of the merged Markov process and of the limit diffusion process too.

Concluding Remarks

Detailed definitions of random evolutions, in semi-Markov and Markov media, can be found in [5]. Average and diffusion approximation scheme of semi-Markov random evolutions with split and merging of the phase space as well as nonergodic switching processes with applications in reliability can be found in [5]. For more references on random evolutions see books [4, 5, 12–14], and review paper [15] and references thereby.

Apart from the average and diffusion approximation considered here, random evolutions can be used also in Poisson and Lévy approximation schemes, where they are naturally associated to the predictable characteristics in additive semimartingale approach, see, for example, [5, Chapter 7].

Damage Processes

Introduction and Background

There is extensive and burgeoning material on the topic of damage and its associated factors like **aging**, cumulative damage, **degradation**, deterioration, fatigue, health status, and quality of life. This material appears in both the biostatistical and the engineering reliability literatures. However, these notions suffer from the feature that they lack a precise definition. Rather they convey an abstract but intuitive import in the sense of a decrease in residual (or remaining) life. This decrease in residual life is conceptualized *via* the feature that an item experiencing aging and degradation will fail when the damage hits some barrier or threshold. Alternatively, it is supposed that at inception, every item is endowed with a resource that gets depleted because of damage, and that the item fails when the resource gets exhausted. Thus, for example, to engineers like Bogdanoff and Kozin [1], “Degradation is the irreversible accumulation of damage throughout life that leads to failure.” The term damage is not made precise; however it is claimed that damage reveals itself *via surrogates* or *markers*, such as cracks that grow in size, corrosion, measured wear (i.e., depletion of material), and so on. Similarly, Sobczyk [2] sees fatigue as “a phenomenon which takes place in units experiencing time-varying external actions which manifest in a deterioration of the unit’s resistance to carry its intended loading”. In the biostatistical literature, *aging* pertains to a unit’s position in a state space wherein the probabilities of failure are greater than its former position. Aging manifests itself in terms of biomedical and physical difficulties experienced by individuals, and in certain scenarios, *via* things like low-CD4 cell counts; these serve as biomedical surrogates, or what are known as *biomarkers*.

The markers mentioned above are, in most cases, observable and measurable entities. Much of the recent work on what is known as *degradation modeling* centers around assessing lifetimes *via* an analysis of the observed markers and their hitting times to a threshold (*cf.* Doksum [3], Doksum and Normand [4], Lu and Meeker [5], Ebrahimi [6], and Lehmann [7]). However, treating the observable markers as substitutes for the unobservable degradation process

that actually causes failure is tantamount to putting the cart before the horse. This is because the unobservable degradation process spawns the observable marker process, and is therefore its cause. An exception, however, is the work of Whitmore *et al.* [8] and of Lee *et al.* [9], who treat the degradation and the marker as separate but related processes. Also, see Nair [10], who makes the point that data on the observable surrogates of degradation help *sharpen* lifetime assessments. In this vein, a noteworthy contribution is by Cox [11] who systematically articulates the roles that the observable and the unobservable play in lifetime assessments. The premise upon which our bivariate stochastic process model with a random threshold is based has been inspired by the papers of Whitmore *et al.* [8] and Cox [11], and our work on hazard potential (see Singpurwalla [12; 13, p. 79]).

Preliminaries: The Hazard Potential

For an appreciation of the bivariate stochastic process model as a description of the damage process, some preliminaries on the notion of a hazard potential would be helpful. Accordingly, let T denote the lifetime of a unit and let $h(t)$ be the hazard rate of $P(T \geq t), t \geq 0$; let $H(t) = \int_0^t h(u) du$ be the cumulative hazard function at t . Then it is easy to see that

$$\begin{aligned} P(T \geq t; h(t), t \geq 0) \\ = \exp(-H(t)) = P(X \geq H(t)) \end{aligned} \quad (1)$$

where X has an exponential distribution with scale one. The random variable X is called the *hazard potential* of the item, and it represents an unknown “resource” that the item is endowed with at inception. Furthermore $H(t)$ is a measure of the amount of resource consumed by time t , and $h(t)$, the rate at which the resource is consumed at t . The unit fails when $H(t)$ exceeds X ; that is when $H(t)$ hits the random threshold X .

When the rate at which a unit’s resource gets consumed is random, $h(t)$ is described by a stochastic process, making $\{H(t); t \geq 0\}$ a stochastic process as well. However, this latter process has to be nondecreasing. The unit fails when the process $\{H(t); t \geq 0\}$ hits a barrier X , where X is also random with a unit exponential distribution. Candidate stochastic processes for $\{H(t); t \geq 0\}$ are

also alluded to in Singpurwalla [12]. Since $H(t)$ is, in principle, nondecreasing in t , $t \geq 0$, the process $\{H(t); t \geq 0\}$ is a candidate for describing a damage process. Furthermore, since the conventional view claims that an item fails when the damage hits a threshold, the cumulative hazard and the damage reflect a parallel feature. This motivates us to view the (cumulative) damage as being isomorphic with the cumulative hazard. Doing so makes our perspective different from that which is currently being discussed in literature. Like (cumulative) damage, the cumulative hazard is not observable. However, the cumulative hazard does influence the time to failure. Consequently, the cumulative hazard and the (cumulative) damage are to be seen as *latent variables*, and for that matter, so is the hazard potential X .

A Stochastic Process Model for Damage and its Markers

Because markers are closely linked with damage, any suitable model for the damage process should be accompanied by some sort of description for the markers as well. The most general way to do this would be to assume that the markers are realizations of stochastic processes, just as the (cumulative) damage is a stochastic process. The simplest way to proceed would be to suppose that there is only one marker to focus attention upon, so that a bivariate stochastic process $\{H(t), Z(t); t \geq 0\}$ would be a suitable description of the damage and its marker. As stated in the section titled “Preliminaries: The Hazard Potential”, the process $\{H(t); t \geq 0\}$ is nondecreasing in t . However, the process $\{Z(t); t \geq 0\}$ need not be restricted to being nondecreasing. Indeed, markers such as crack growth and CD4 cell counts fluctuate around some trend, and thus one is free to choose any suitable model for the process $\{Z(t); t \geq 0\}$. A Wiener process appears to be the model of choice, but this need not be so.

Thus to summarize, our proposed model for the (cumulative) damage and its associated marker is a bivariate stochastic process $\{H(t), Z(t); t \geq 0\}$ with $H(t)$ nondecreasing in t , and $Z(t)$ free to fluctuate around some constant or trend. We term such a process a *degradation process*. Since $H(t)$ spawns $Z(t)$, the two processes $\{H(t); t \geq 0\}$ and $\{Z(t); t \geq 0\}$ need to be linked; that is, they need

to be *cross-correlated*. Without such linkage, the marker process cannot serve as predictor of failure, and the statistical exercise of degradation modeling is not meaningful. One way to achieve this linkage is to describe $\{Z(t); t \geq 0\}$ by a Wiener process, and the unobservable (cumulative) damage process by a *Wiener maximum process*, namely,

$$H(t) = \sup_{0 \leq s \leq t} \{Z(s); s \geq 0\} \quad (2)$$

This strategy has been proposed in Singpurwalla [14], wherein a Bayesian approach for inference about lifetimes, using data on the marker process, is also described. The item fails when $H(t)$ hits the (random) threshold X . Whereas the model of equation (2) could be a starting point, there is a *caveat* that needs to be addressed. Specifically, since $Z(t)$ is spawned by $H(t)$, the latter is the cause of the former. This means that $H(t)$ must lead $Z(t)$, and so any linkage between the two processes in question should incorporate a time lag. The model of equation (2) does not do this because here $H(t)$ is determined retrospective to $Z(t)$ and therefore lags $Z(t)$, instead of the other way around. Thus $H(t)$ and $Z(t)$ need to be connected, with the observable $Z(t)$ lagging the unobservable $H(t)$. This is a possible topic for future research.

In the section titled “Candidate Processes for Damage and Markers”, we give an overview of some modeling strategies that have been proposed for the damage process $\{H(t); t \geq 0\}$, as well as for the marker process $\{Z(t); t \geq 0\}$ when each are treated separately; that is when no distinction is made between the damage (or degradation) process and the marker process. Supplementary material on the above can also be found in Chapters 7 and 8 of Singpurwalla [13].

Candidate Processes for Damage and Markers

The origins of the work on threshold crossing of cumulative damage as a basis for failure goes back to Epstein [15], Esary [16], and Gaver [17]. The idea of describing cumulative damage as a stochastic process can be traced, to the best of our knowledge, to Cox [18, p. 91], and to the Ph.D. thesis of Morey [19]. However, the granddaddy of all work on damage processes is the remarkable paper of Esary

et al. [20], who (without articulating what damage means) describe damage by a compound **Poisson process** with increments that are positive and have the Markov property. Failure occurs when the said process hits a random barrier whose distribution is exponential. The choice of an exponential distribution for the barrier is arbitrary, and Esary *et al.* [20] show that the hitting time has an exponential distribution. More recently Zacks [21, 22] has elaborated on this theme.

In the biostatistical arena there is a setup parallel to that of Esary *et al.* [20], which does not allude to damage, deterioration, or aging, but to the number of mice at some time t , that have typhoid organisms. The growth of such mice is described by a pure birth process, and the first passage time to a barrier is investigated. The specifics are in Cox and Miller [23, p. 160], and in Cox [11].

The Esary *et al.* [20] architecture is enhanced by Lemoine and Wenocur [24], who model wear (i.e., damage) by a suitable random process but who also allow for failure due to trauma. The latter is described by a Poisson process, the rate of which depends on the state of wear. An item fails when the wear reaches a threshold or when the item experiences fatal trauma. Thus in the model of Lemoine and Wenocur [24], the wear and the trauma processes compete with each other for an item's lifetime. The random process considered by the above authors is a diffusion process that is driven by a Wiener process. In a subsequent paper, Lemoine and Wenocur [25] describe wear by a shot-noise process. A disadvantage of the diffusion and the shot-noise process is that the wear (to us damage) is not monotonically nondecreasing. To rectify this deficiency, Wenocur [26] considers a gamma process for describing wear. His development of the gamma process proceeds along the following lines.

Partition the time interval into subintervals of length h , and let $X(n)$ denote the damage (or wear) at time nh , $n = 1, 2, \dots$. Suppose that the damage at time $(n+1)h$ is prescribed *via* the relationship

$$X(n+1) - X(n) = \alpha(X(n))\varepsilon_n + \beta(X(n))h \quad (3)$$

where α, β are constants, and $\{\varepsilon_n\}$ is a sequence of independent and identically distributed random variables having a gamma distribution with shape parameter $h > 0$. Letting $h \downarrow 0$, we have

$$dX(t) = \alpha(X(t^-)) d\gamma(t) + \beta(X(t^-)) \quad (4)$$

where $\{\gamma(t)\}$ is a *gamma process*.

In integral terms, equation (4) becomes the *stochastic integral*

$$X(t) = X(0) + \int_0^t \alpha(X(s^-)) d\gamma(s) + \int_0^t \beta(X(s^-)) ds \quad (5)$$

Since the gamma process has nonnegative increments, the wear (or damage) process is increasing. For an overview of the gamma process and their constructions, see Singpurwalla [27], or van der Weid [28]. Whereas a gamma process model may be attractive in scenarios wherein the damage causing shocks occur frequently, the models by Zacks [21, 22] for the compound Poisson process case and for the compound renewal process case, respectively, seem to be more appropriate when the shocks are infrequent.

Candidate Marker Processes

In engineering reliability, an archetypical marker process is crack growth, whereas in biostatistical studies, it appears that CD4 cell counts is a commonly mentioned biomarker. With archetypical markers come archetypical stochastic processes for $\{Z(t); t \geq 0\}$, and one such process is the Wiener process with a drift parameter η and a diffusion parameter $\sigma^2 > 0$; see Doksum [3] and Whitmore *et al.* [8]. As mentioned before, the marker is often viewed as a proxy for damage, and failure is said to occur when the marker process hits a threshold. As is well known, the hitting time to the threshold (assumed fixed and known) of a Wiener process has an *inverse Gaussian distribution* (see Singpurwalla [13, p. 68 and 136], for a discussion of this distribution).

The Wiener process has independent increments, so does a gamma process. This amounts to saying that the increments of crack size are independent of the existing crack length. This latter phenomenon is not always true. The bigger the crack, the bigger is its growth. This motivates one to consider transformations of the Wiener process. Furthermore, the crack growth phenomenon also exhibits abrupt growth. The Wiener process does not encapsulate such abruptness of growth. With the above in mind, Schabe [29] proposes the following as a model for $X(t)$, the size of a crack at time t , $t \geq 0$. Let $X(t) = (M(t))^a$, where

$$M(t) = bt + W(t) + \mu P(t) \quad (6)$$

Here $W(t)$ is a Wiener process with variance $\sigma^2 t$, and $P(t)$ is a Poisson process with intensity

4 Damage Processes

λ . The constant $b \geq 0$ describes a trend, and the constant a is such that $a > (<)1$ encapsulates a progressive (regressive) velocity with which the crack grows. Under the model of equation (6), Schabe [29] obtains the hitting time of $X(t)$ to $h > 0$, a barrier. This distribution does not have a closed-form solution. However, the mean and the variance of this distribution are available; these are $h^{h/a}(b + \mu\lambda)$ and $h^{1/a}(\sigma^2 + \lambda\mu^2)/(b + \mu\lambda)^3$, respectively.

In Ebrahimi [6], a strategy that parallels those of Lemoine and Wenocur [24] and of Schabe [29] is taken, but instead of looking at the growth of a single crack, an ensemble of k cracks, each having its own growth rate is considered. Specifically, it is supposed that the growth of the i th crack, $i = 1, \dots, k$ is governed by the stochastic differential equation

$$dX_i(t) = \lambda_i(t)X_i(t) + \sigma X_i(t) dW(t) \quad (7)$$

where $\lambda_i(t)$ is the growth rate of the cracks, $\sigma > 0$ is a constant, and $\{W(t); t \geq 0\}$ is a standard Wiener process with mean 0 and variance t . Using standard results (i.e., the Ito formula) it can be seen that

$$X_i(t) = X(0) \exp \left[\Lambda_i(t) - \frac{\sigma^2}{2}t + \sigma W(t) \right] \quad (8)$$

where $\Lambda_i(t) = \int_0^t \lambda_i(s) ds$, and $X(0)$ is the initial crack size, assumed to be known, and is the same for all the k cracks. The item fails when the size of the largest crack hits some threshold, say a . If T denotes the passage time of the largest crack to the threshold a , then it can be seen that for $0 \leq u \leq t$

$$P(T \geq t) = P \left[W(u) < \left(\min_{1 \leq i \leq k} \left(\frac{\sigma}{2}u - \frac{1}{\sigma} \Lambda_i(u) \right) + c \right) \right] \quad (9)$$

where $c = b/\sigma$ and $b = \log a - \log X(0)$.

Computation of the above follows from results on the the times taken by the Weiner process to hit a threshold.

Motivated by a model of Durham and Padgett [30], Park and Padgett [31] propose a model for cumulative damage, assuming that the damage is an observable measurable entity. This amounts to interpreting cumulative damage as a marker, like crack growth. The scheme proposed by Park and Padgett [31] is noteworthy, because it facilitates the introduction of both a **Brownian motion** process and

a gamma process as the driving processes for crack growth. Here, for some functions $c(\cdot)$ and $h(\cdot)$, it is assumed that

$$dc(X(t)) = h(X(t)) dD(t) \quad (10)$$

where $D(t)$ is the damage at t , and $X(t)$ is the cumulative damage at t . As a consequence of the above

$$\int_0^t \frac{1}{h(X(u))} dc(X(u)) = \int_0^t dD(u) = D(t) - D(0) \quad (11)$$

By choosing various forms for the function $c(\cdot)$ and $h(\cdot)$, and a stochastic process for $\{D(t); t \geq 0\}$, different models for $X(t)$ can be attained. For example, with $h(u) = 1$, $c(u) = \log u$, and a Brownian motion (or Wiener process) for $\{D(t); t \geq 0\}$, we obtain a geometric Brownian motion process for $X(t)$. With $h(u) = 1$, $c(u) = u$ and a Brownian motion process for $\{D(t); t \geq 0\}$ we obtain a Gaussian process for $X(t)$. With $h(u) = 1$, $c(u) = u$ and a gamma process for $\{D(t); t \geq 0\}$ we obtain a gamma process for $X(t)$. Whereas the Gaussian process is not always positive, the geometric Brownian motion process is always positive but not increasing. In contrast, the gamma process is both positive and increasing. Characteristics of the hitting times of the geometric Brownian motion and the gamma process to a fixed and known threshold are also obtained by Park and Padgett [31]. This completes our overview of stochastic process models for the damage process and the marker process – when viewed separately – save for the work of Desmond [32], who articulates on a two-parameter family of life distributions introduced by Birnbaum and Saunders [33]. This distribution is motivated *via* the notion that failure caused by fatigue is due to the initiation, growth, and extension of a dominant crack past some critical length.

The essence of Desmond's [32] idea is based on the notion that it is the environmental stresses called *impulses* that cause a crack to grow, so that if X_i is the size of the crack after the i th impulse, then

$$X_{i+1} = X_i + \Pi_{i+1}g(X_i), i = 0, 1, 2, \dots \quad (12)$$

here Π_i is taken to be the magnitude of the i th impulse; e.g. the stress caused by the i th impulse. The Π_i 's are assumed to be random. If $\nabla X_i = X_{i+1} - X_i$

is taken to be sufficiently small, then

$$\sum_1^n \Pi_i \approx \int_{X_0}^{X_n} \frac{dy}{g(y)} \quad (13)$$

is approximately normal; $g(y)$ is some function of y . The quantity X_0 is the initial size of the dominant crack.

With $g(y) = 1$, and assuming that the Π_i 's have a common mean μ and variance σ^2

$$I(X(t)) \stackrel{\text{def}}{=} \int_{X_0}^{X_n} \frac{dy}{g(y)} \sim N(t\mu, t\sigma^2) \quad (14)$$

If X_c denotes the critical crack size, and T the time to failure of the unit experiencing the impulses, then

$$T = \inf \{t: X(t) > X_c\} \quad (15)$$

Simple manipulations show that

$$P(T \leq t) = \Phi \left(\frac{t\mu - I(X_c)}{\sigma\sqrt{t}} \right) \quad (16)$$

Where $\Phi(\cdot)$ is the unit **normal distribution** function. The distribution function given above is a member of the Birnbaum–Saunders [33] family of distributions.

Precedence Tests

Review on Precedence-Type Procedures

In measuring reliability, we observe lifetimes of products or systems of interest. In order to gain a sound knowledge about product or system failure-time distributions, *life-testing and reliability experiments* are carried out before (and while) products are put on the market or systems are used. Life-testing experimentation is a practical way to determine the product reliability and product quality. During the life test, successive times to failure are noted and lifetime data are thus collected. These lifetime data are often used to make decisions on accepting a new design over an existing design. Life testing is useful in many industrial environments including the automobile, materials, chemical, telecommunications, electronics, and pharmaceutical industries. For instance, a manufacturer of electronic components may wish to compare two designs A and B in terms of life. Specifically, he/she may want to abandon design A if there is evidence at the 0.05 level that it has shorter life in comparison to design B.

Assume that a random sample of n_1 units is from F_X (existing design), another independent sample of n_2 units is from F_Y (new design), and that all these sample units are placed simultaneously on a life-testing experiment. We use $X_1, X_2, \dots, X_{n_1}$ to denote the sample from distribution F_X , and $Y_1, Y_2, \dots, Y_{n_2}$ to denote the sample from distribution F_Y . A natural null hypothesis is that the two distributions are equal (i.e., there is no difference between the existing design and the new design) and we are generally concerned with the alternative models where one distribution is stochastically larger than the other; for example, the alternative that F_Y is stochastically larger than F_X (the new design produces units with longer life as compared to the existing design) which can be expressed as

$$H_0 : F_X = F_Y \text{ against } H_1 : F_X > F_Y \quad (1)$$

There has been a considerable amount of research work carried out on this problem from a nonparametric point of view; for more details, see the books [1–5].

In order to save on test time and/or to save on the number of test items, it is common that not all

the items under test will be observed until failure in an industrial setting. In other words, some of the test items will be withdrawn or removed from the life test. This situation is known as *censoring*. For example, in the situation mentioned above with regard to making a decision on accepting a new design over an existing design, usually the cost of producing items from the new design will be much higher than the cost of producing items from the existing design; therefore, we may decide to observe only a few failures (say, the first r failures) from the new design in order to save a number of items that could potentially be used for some other tests. In this scenario, *precedence test* is useful to test the hypotheses in equation (1). The precedence test is a distribution-free two-sample life test based on the order of early failures, and was first proposed by Nelson [6]. The precedence test allows a simple and robust comparison of two distribution functions. Precedence test, based on the number of X failures that precede the r th Y failure, will be useful (a) when life tests involve expensive units since the units that had not failed could be used for some other testing purposes, and (b) to make quick and reliable decisions early on in the life-testing experiment.

We denote the order statistics from the X sample and the Y sample by $X_{1:n_1} \leq X_{2:n_1} \leq \dots \leq X_{n_1:n_1}$ and $Y_{1:n_2} \leq Y_{2:n_2} \leq \dots \leq Y_{n_2:n_2}$, respectively. Without loss of generality, we assume that $n_1 \leq n_2$. Moreover, we let M_1 be the number of X failures before $Y_{1:n_2}$ and M_i be the number of X failures between $Y_{i-1:n_2}$ and $Y_{i:n_2}$, $i = 2, 3, \dots, r$. We denote the observed value of M_i by m_i . It is of interest to mention here that these M_i 's are related to the so-called exceedance statistics whose distributional properties have been discussed, for example, by Fligner and Wolfe [7] and Randles and Wolfe [2].

Nelson [6] provided tables of critical values, which cover all combinations of sample sizes up to 20 for one-sided (two-sided) significance levels of 0.05 (0.10), 0.025 (0.05), and 0.005 (0.01). After Nelson [6] first introduced the precedence life test, many authors have studied the **power** properties of the precedence test and have also proposed some alternatives. For example, Eilbott and Nadler [8] investigated the properties of precedence tests under the assumption that both underlying distributions are exponential. They obtained closed-form expressions for the small-sample and asymptotic power under the exponential distribution. Then, Shorack [9] actually showed that these expressions are valid for a large

2 Precedence Tests

class of distributions. Subsequently, Young [10] presented some asymptotic results for the precedence test. He also applied the precedence sampling to a population selection problem concerning population **quantiles**. Katzenbeisser [11] derived the distribution as well as the first two **moments** of precedence (he used the term *exceedance* instead) test statistics under Lehmann alternatives. Moreover, Katzenbeisser [12] studied the exact power of two-sample location tests based on precedence test statistics against shifts in exponential, logistic, and rectangular distributions. Liu [13] investigated the properties of the precedence probabilities and their applications, while Lin and Sukhatme [14] considered the best precedence test and compared the power of the best precedence test with other nonparametric and **parametric tests**.

Nelson [15] examined the power of the precedence test when the underlying distributions were normal. After Lin and Sukhatme [14] discussed the best precedence test, van der Laan and Chakraborti [16] used their results to derive the best precedence test under Lehmann alternatives. Recently, a book by Balakrishnan and Ng [17] provides a comprehensive overview of theoretical and applied results relating to a wide variety of problems in which precedence test and its alternatives have been used. They have demonstrated the effectiveness of these tests in life-testing situations designed for making quick and reliable decisions in the early stages of a life-testing experiment.

Precedence Test

Following the aforementioned setting and notation, the precedence test statistic $P_{(r)}$ is defined as the number of failures from the X sample that precede

the r th failure from the Y sample; that is,

$$P_{(r)} = \sum_{i=1}^r M_i \quad (2)$$

For example, from Figure 1, with $r = 4$, the precedence test statistic takes on the value $P_{(4)} = 0 + 3 + 4 + 1 = 8$.

It is evident that large values of $P_{(r)}$ lead to the rejection of H_0 in equation (1). For a fixed level of significance α , the critical region will be $\{s, s + 1, \dots, n_1\}$, where

$$\alpha = \Pr(P_{(r)} \geq s | F_X = F_Y) \quad (3)$$

For specified values of n_1, n_2, s , and r , an expression for α in equation (3) is given by

$$\alpha = \frac{\sum_{j=s}^{n_1} \binom{s+r-1}{j} \binom{n_1+n_2-s-r+1}{n_1-j}}{\binom{n_1+n_2}{n_2}} \quad (4)$$

with the summation terminating as soon as any of the factorials involve negative arguments. The critical value s and the exact level of significance α , as close as possible to 5 and 10%, are presented in Balakrishnan and Ng [17] for different choices of the sample sizes n_1 and n_2 and r .

Maximal Precedence Test

Since the precedence test is based on the sum of the frequencies of failures from the X sample between

Figure 1 Schematic representation of a precedence life test

the first r failures of the Y sample, it does not take into consideration the distribution of these frequencies of failures. As a result, there will be a *masking effect* present. Balakrishnan and Frattina [18] noted that such a “masking effect” affects the performance of the precedence test and, therefore, proposed a maximal precedence test which is based on the maximum of the numbers of X failures occurring before the first and between the first and second Y -failures. Balakrishnan and Ng [19] generalized this procedure for up to r Y failures which is called *general maximal precedence test*. It is a test procedure based on the maximum number of failures occurring from the X sample before the first, between the first and the second, ..., between the $(r - 1)$ th and the r th failures, from the Y sample. It is a test procedure useful for testing the hypotheses in equation (1) and it avoids the masking effect.

With the same notation as above, the general maximal precedence test statistic is defined as

$$M_{(r)} = \max(M_1, M_2, \dots, M_r) \quad (5)$$

For example, if we refer to Figure 1, with $r = 4$, the maximal precedence test statistic is $M_{(4)} = \max(0, 3, 4, 1) = 4$. Large values of $M_{(r)}$ will lead to the rejection of H_0 and in favor of H_1 in equation (1). The null distribution of $M_{(r)}$, for the special case when $r = 2$, was derived by Balakrishnan and Frattina [18]. Subsequently, Balakrishnan and Ng [19] derived the joint distribution of $M_1, \dots, M_r$, under $H_0 : F_X = F_Y$, as

$$\begin{aligned} \Pr(M_1 = m_1, \dots, M_r = m_r \mid F_X = F_Y) \\ = \frac{\binom{n_1 + n_2 - \sum_{i=1}^r m_i - r}{n_2 - r}}{\binom{n_1 + n_2}{n_2}} \quad (6) \end{aligned}$$

and they used equation (6) to derive the null distribution of the general maximal precedence test statistic $M_{(r)}$ for $r \geq 2$. They examined the power properties of the maximal precedence test and compared them with those of the precedence test and Wilcoxon's rank-sum test (based on complete samples). Through their simulation work, they demonstrated that the maximal precedence test does

avoid the masking effect affecting the precedence test.

Wilcoxon-Type Precedence Test

We can see that even though an alternative to the precedence test has been proposed in the form of maximal precedence test, it too is based on frequencies of failures preceding the r th Y failure. Although Balakrishnan and Ng [19] demonstrated that the maximal precedence test does avoid the masking effect, it still suffers from a loss of power when compared to the classical Wilcoxon's rank-sum test (based on complete samples). For this reason, Ng and Balakrishnan [20, 21] extended the precedence test in another way by constructing Wilcoxon-type rank based precedence test that takes into account the magnitude of the failure times.

The Wilcoxon rank-sum test is a well-known non-parametric testing procedure for testing the hypothesis in equation (1) based on complete samples. For testing the hypotheses in equation (1), if complete samples of sizes n_1 and n_2 were available, then one can use the standard Wilcoxon's rank-sum statistic, proposed by Wilcoxon [22], which is simply the sum of ranks of X observations in the combined sample.

Ng and Balakrishnan [20] proposed the Wilcoxon-type rank-sum precedence tests for testing the hypotheses in equation (1) when the Y sample is Type-II censored. This test is a variation of the precedence test and a generalization of the Wilcoxon rank-sum test. Three Wilcoxon-type rank-sum precedence test statistics – the minimal, maximal, and expected rank-sum statistics – have been proposed by these authors. In order to test the hypotheses in equation (1), instead of using the maximum of the frequencies of failures from the X sample between the first r failures of the Y sample, one could use the sum of the ranks of those failures. More specifically, suppose $m_1, m_2, \dots, m_r$ denote the number of X failures that occurred before the first, between the first and the second, ..., between the $(r - 1)$ th and the r th Y failures, respectively; see Figure 1. Let W be the rank sum of the X failures that occurred before the r th Y failure. The Wilcoxon's test statistic will be smallest when all the remaining $(n_1 - \sum_{i=1}^r m_i)$ X failures occur between the r th and $(r + 1)$ th Y failures. The test statistic in this case

4 Precedence Tests

would be

$$\begin{aligned}
 W_{\min,r} &= W + \left[\left(\sum_{i=1}^r m_i + r + 1 \right) \right. \\
 &\quad \left. + \left(\sum_{i=1}^r m_i + r + 2 \right) + \cdots + (n_1 + r) \right] \\
 &= \frac{n_1(n_1 + 2r + 1)}{2} - (r + 1) \sum_{i=1}^r m_i + \sum_{i=1}^r i m_i
 \end{aligned} \tag{7}$$

This is called the *minimal rank-sum statistic*.

The Wilcoxon's test statistic will be the largest when all the remaining $(n_1 - \sum_{i=1}^r m_i)$ X failures occur after the n_2 th Y failure. Such a test statistic is called the *maximal rank-sum statistic* and is given by

$$\begin{aligned}
 W_{\max,r} &= \frac{n_1(n_1 + 2n_2 + 1)}{2} \\
 &\quad - (n_2 + 1) \sum_{i=1}^r m_i + \sum_{i=1}^r i m_i
 \end{aligned} \tag{8}$$

We could similarly propose a rank-sum statistic using the expected rank sums of failures from the first sample between the r th and the $(r + 1)$ th, ..., after the n_2 th failures of the second sample, denoted by $W_{E,r}$. It can be shown that $W_{E,r}$ is simply the average of $W_{\min,r}$ and $W_{\max,r}$, and is given by

$$\begin{aligned}
 W_{E,r} &= \frac{n_1(n_1 + n_2 + r + 1)}{2} \\
 &\quad - \left(\frac{n_2 + r}{2} + 1 \right) \sum_{i=1}^r m_i + \sum_{i=1}^r i m_i
 \end{aligned} \tag{9}$$

For example, from Figure 1, when $n_1 = n_2 = 10$ with $r = 4$, we have

$$\begin{aligned}
 W_{\min,4} &= 2 + 3 + 4 + 6 + 7 + 8 + 9 \\
 &\quad + 11 + 13 + 14 = 77, \\
 W_{\max,4} &= 2 + 3 + 4 + 6 + 7 + 8 + 9 \\
 &\quad + 11 + 19 + 20 = 89, \\
 W_{E,4} &= \frac{77 + 89}{2} = 83
 \end{aligned} \tag{10}$$

It is evident that small values of $W_{\min,r}$, $W_{\max,r}$, and $W_{E,r}$ lead to the rejection of H_0 and in favor of H_1 in equation (1). Moreover, in the special case of $r = n_2$ (i.e., when we observe all the failures from the Y sample), we have $W_{\min,n_2} = W_{\max,n_2} = W_{E,n_2}$ and in this case they are all equivalent to the classical Wilcoxon's rank-sum statistic mentioned earlier.

Ng and Balakrishnan [21] derived the null distributions of these three Wilcoxon-type rank-sum precedence test statistics based on equation (6), while Ng and Balakrishnan [20] observed that the large-sample normal approximation for the null distribution is not satisfactory in the case of small or moderate sample sizes. For this reason, they developed an Edgeworth expansion to approximate the significance probabilities. They also derived the exact power function under the Lehmann alternative and examined the power properties of the Wilcoxon-type rank-sum precedence tests under a location-shift alternative through extensive **Monte Carlo** simulations.

Weighted Precedence and Maximal Precedence Tests

Weighted precedence and maximal precedence tests for testing the hypotheses in equation (1) is another logical extension of the precedence and maximal precedence tests. The motivation for this is explained in the following two cases based on the example mentioned earlier.

Example 1 A manufacturer of electronic components wishes to compare two designs A and B in terms of their life lengths. Specifically, he/she wishes to abandon design A if there is enough evidence at 5% level of significance that it has shorter life in comparison to design B. $n_1 = 10$ components from design A and $n_2 = 10$ components from design B are placed simultaneously on a life test, and the test is to be terminated when the 5th failure from design B occurs. Figures 2 and 3 show two possible outcomes of the life-testing experiment in this example.

The precedence and maximal precedence test statistics are equal in both cases, and they are $P_{(5)} = 8$ and $M_{(5)} = 5$. We have the critical values with $n_1 = n_2 = 10$ and $r = 5$ as 9 (with level of significance 0.02864) and 6 (with level of significance 0.02709) for the precedence and maximal precedence tests, respectively. Therefore, we will not reject the null

Figure 2 Case 1 of the precedence life test for Example 1

Figure 3 Case 2 of the precedence life test for Example 1

hypothesis that two distributions are equal in both cases at the same level of significance. However, we feel that Case 2 provides much more evidence that design B is better than design A. This suggests that we should develop a test procedure that distinguishes Cases 1 and 2. On this basis, Ng and Balakrishnan [23] proposed the weighted precedence and maximal precedence tests.

The weighted precedence and maximal precedence tests are defined by giving decreasing weights to m_i for increasing i . For example, the weighted precedence test statistic $P_{(r)}^*$ is defined as

$$P_{(r)}^* = \sum_{i=1}^r (n_2 - i + 1) m_i \quad (11)$$

and the weighted precedence test statistic $M_{(r)}^*$ is defined as

$$M_{(r)}^* = \max_{1 \leq i \leq r} \{(n_2 - i + 1) m_i\} \quad (12)$$

For example, from Figure 1, when $n_1 = n_2 = 10$ with $r = 4$, we have

$$\begin{aligned} P_{(4)}^* &= (9 \times 3) + (8 \times 4) + (7 \times 1) = 66, \\ M_{(4)}^* &= \max \{(9 \times 3), (8 \times 4), (7 \times 1)\} = 32 \end{aligned} \quad (13)$$

Once again, it is clear that large values of $P_{(r)}^*$ or $M_{(r)}^*$ would lead to the rejection of H_0 and in favor of H_1 in equation (1).

Ng and Balakrishnan [23] derived the null distributions of these test statistics and the exact power functions under the Lehmann alternative. They also compared the power (under location shift) of the weighted precedence and maximal precedence tests with those of the original precedence and maximal precedence tests.

We note here that in a precedence test, since the life testing continues until the occurrence of the r th Y failure, it may be viewed as a test based on a Type-II right censored Y sample. Therefore, if we want to save the testing units at the early stage of the life test,

a Type-II progressive censoring scheme may instead be employed on the Y sample. For a comprehensive treatment on progressive censoring, one may refer to Balakrishnan and Aggarwala [24]. This will then be a logical extension of the precedence and maximal precedence tests.

Suppose a Type-II progressive censoring scheme is to be adopted on the Y sample which means that a number $r < n_2$ is prefixed for the number of complete failures to be observed and the censoring scheme $(R_1, R_2, \dots, R_r)$ with $R_j \geq 0$ and $\sum_{j=1}^r R_j + r = n_2$ is to be employed at the failure times. During the life-testing experiment, at the time of the j th failure, R_j functioning items are randomly removed from the test. We denote such an observed ordered Y sample by $Y_{1:r:n_2} \leq Y_{2:r:n_2} \leq \dots \leq Y_{r:r:n_2}$. Moreover, we denote by M_1 the number of X failures before $Y_{1:r:n_2}$ and by M_i the number of X failures between $Y_{i-1:r:n_2}$ and $Y_{i:r:n_2}$, $i = 2, 3, \dots, r$.

An extension of the weighted precedence and weighted maximal precedence tests to Type-II progressive censoring has been discussed by Ng and Balakrishnan [23] and Balakrishnan and Ng [17]. Then, based on $M_1, M_2, \dots, M_r$ obtained under Type-II progressive censoring on the Y sample with censoring scheme $(R_1, R_2, \dots, R_r)$, we propose the weighted precedence test statistic $P_{(r)}^*$ (analogous to equation (11)) as

$$P_{(r)}^* = \sum_{i=1}^r \left[n_2 - \left(\sum_{j=1}^{i-1} R_j \right) - i + 1 \right] m_i \quad (14)$$

and the weighted maximal precedence test statistic $M_{(r)}^*$ (analogous to equation (12)) as

$$M_{(r)}^* = \max_{1 \leq i \leq r} \left\{ \left[n_2 - \left(\sum_{j=1}^{i-1} R_j \right) - i + 1 \right] m_i \right\} \quad (15)$$

For example, from Figure 4, with $n_2 = 10$, $r = 4$ and censoring scheme $(2, 1, 1, 2)$, the weighted precedence test statistic becomes $P_{(4)}^* = (10 \times 0) + (7 \times 3) + (5 \times 4) + (3 \times 1) = 44$, while the weighted maximal precedence test statistic becomes $M_{(4)}^* = \max\{(10 \times 0), (7 \times 3), (5 \times 4), (3 \times 1)\} = 21$. It is clear that large values of $P_{(r)}^*$ or $M_{(r)}^*$ would lead to the rejection of H_0 and in favor of H_1 in equation (1).

It is important to mention here that the weighted precedence and maximal precedence test statistics defined earlier in equations (11) and (12) become special cases when we set $R_1 = R_2 = \dots = R_{r-1} = 0$ and $R_r = n_2 - r$.

Exact Power under Lehmann Alternative

The Lehmann alternative $H_1 : [F_X]^\gamma = F_Y$ for some γ is a subclass of the alternative $H_1 : F_X > F_Y$ when $\gamma > 1$; see Lehmann [1] and Gibbons and Chakraborti [5]. The joint probability mass function of $M_1, \dots, M_r$ under the Lehmann alternative is

$$\Pr\{M_1 = m_1, \dots, M_r = m_r \mid [F_X]^\gamma = F_Y\}$$

Figure 4 Schematic representation of a precedence life test with progressive censoring

$$\begin{aligned}
&= \frac{n_1!n_2!\gamma^r}{m_1!(n_2-r)!} \left\{ \prod_{j=1}^{r-1} \frac{\Gamma\left(\sum_{i=1}^j m_i + j\gamma\right)}{\Gamma\left(\sum_{i=1}^{j+1} m_i + j\gamma + 1\right)} \right\} \\
&\quad \times \sum_{k=0}^{n_2-r} \binom{n_2-r}{k} (-1)^k \\
&\quad \times \frac{\Gamma\left(\sum_{i=1}^r m_i + (r+k)\gamma\right)}{\Gamma(n_1 + (r+k)\gamma + 1)} \quad (16)
\end{aligned}$$

The power of a test is the probability of rejecting the null hypothesis when the alternative hypothesis is indeed true. So under the Lehmann alternative, the power function for the precedence test and its alternatives can be determined. Note that the null distribution of the test procedures are obtained simply by putting $\gamma = 1$ in the above formulas. We can see that $H_1 : [F_X]^\gamma = F_Y$ is a subclass of the alternative $H_1 : F_X > F_Y$ when $\gamma > 1$.

The power values of the precedence, maximal precedence, weighted precedence, weighted maximal precedence, and Wilcoxon-type rank-sum precedence tests under the Lehmann alternative have all being computed and presented in Balakrishnan and Ng [17]. From those values, it is seen that the Wilcoxon-type rank-sum precedence tests discussed here give higher power values under the Lehmann alternative for all the cases considered.

With a Type-II progressive censoring scheme $(R_1, R_2, \dots, R_r)$ on the Y sample, under the Lehmann alternative $[F_X]^\gamma = F_Y$, $\gamma > 1$, the joint probability mass function of $M_1, M_2, \dots, M_r$ is given by

$$\begin{aligned}
&\Pr(M_1 = m_1, M_2 = m_2, \dots, M_r = m_r \mid [F_X]^\gamma = F_Y) \\
&= C\gamma^r \sum_{j_i (i=1,2,\dots,r)=0}^{R_i} \binom{R_1}{j_1} \binom{R_2}{j_2} \cdots \binom{R_r}{j_r} \\
&\quad \times (-1)^{\left(\sum_{i=1}^r j_i\right)} \\
&\quad \times \left\{ \prod_{k=1}^{r-1} B\left(\sum_{i=1}^k m_i + \gamma\left(\sum_{i=1}^k j_i\right) + k\gamma, m_{k+1} + 1\right) \right\}
\end{aligned}$$

$$\begin{aligned}
&\times B\left(\sum_{i=1}^r m_i + \gamma\left(\sum_{i=1}^r j_i\right) + r\gamma, n_1 - \sum_{i=1}^r m_i + 1\right) \quad (17)
\end{aligned}$$

Note that when $R_1 = R_2 = \dots = R_{r-1} = 0$ and $R_r = n_2 - r$, the joint probability mass function in equation (17) reduces to the expression in equation (16). The exact power values for different choices of n_1, n_2, r , and γ for several progressive censoring schemes have been computed and presented in Balakrishnan and Ng [17].

Selection of the Best Population

When we have two or more competing populations, a problem of interest often is to make a decision as to which is the best if we reject the null (homogeneity) hypothesis in equation (1). In the literature of ranking and selection methodology, parametric and nonparametric procedures for selecting the best among k populations based on samples from these populations have been discussed in great detail; see, for example, Bechhofer *et al.* [25], Gibbons *et al.* [26], and Gupta and Panchapakesan [27]. In order to select the best population based on observing only a few failures from two or more samples under life testing, test procedures based on the nonparametric precedence-type statistics with selecting the best population as an objective in the alternative hypotheses will be useful, especially when budget and/or facility constraints are in place in an industrial setting.

Recently, Balakrishnan *et al.* [28] proposed a nonparametric test procedure based on the precedence statistic to test the equality of two distributions against alternatives that a specified population is better than the other. They also studied the k -sample situation and showed that the procedure works well for different underlying distributions by means of Monte Carlo simulations. Similarly, Ng *et al.* [29] used the minimal Wilcoxon rank-sum precedence statistic instead of the precedence statistic to select the best population based on a test for equality. They also compared the probabilities of correct selection of the minimal Wilcoxon rank-sum precedence statistic with those of the precedence statistic and showed that the performance of minimal Wilcoxon rank-sum precedence statistic is better for selecting the

best population. For more details about the use of precedence-type statistics in ranking and selection, one may refer to the recent book by Balakrishnan and Ng [17].

Change-Point Models

Introduction

Change-point models have originally been developed in connection with applications in **quality control**, where a change from the *in-control* to the *out-of-control* state has to be detected based on the available random observations. Up to now, various change-point models have been suggested for a broad spectrum of applications like quality control, reliability, econometrics, or medicine.

The general change-point problem can be described as follows: a random process indexed by time is observed and we want to investigate whether a change in the distribution of the random elements occurs. In other words, we are interested in determining whether the observed stochastic process is homogeneous. Formally, in the discrete-time case, let $X_1, X_2, \dots$ denote a sequence of independent random variables, where the elements $X_1, \dots, X_{\theta-1}$ have an identical distribution function F_0 and $X_\theta, X_{\theta+1}, \dots$ are distributed according to F_1 and the change point θ is unknown. Several statistical tests of the null hypothesis $F_0 = F_1$ against the alternative $F_0 \neq F_1$ for some $\theta > 1$ have been suggested. In addition, estimates for the change point have been proposed and their properties have been investigated. A lot of work has been done in this research field and it is impossible to give an exhaustive overview. The Zentralblatt MATH returns almost 3000 hits, when entering the word “change point”.

Change-point problems can be classified in different ways. Approaches in the classical framework as in the Bayesian framework have been made. Also, there exist models in continuous time as well as in discrete time. Furthermore, the analysis of change points can be partitioned in sequential and *a posteriori* detection models (*ex post* analysis). The problem can also be viewed in a parametric or nonparametric context. Another characterization is whether only one or more than one change points exist. The early work in change-point analysis is described in the survey article of [1]. Other comprehensive reviews are given in [2] and in [3] for nonparametric models. For an overview of limit theorems in change-point problems, we refer to [4]. Change-point methods in **process control** are extensively studied in **Change-point methods**. In this article, we want to concentrate

on a review of models and methods for sequentially observed data and for change points in regression and hazard rate models. We contemplate methods used for sequentially observed data in discrete and continuous time in the first section. The second section presents an overview of change points in regression and hazard rate models. The selection of models follows our personal view.

Detection of a Change Point in Sequentially Observed Data

The aim of so-called disorder or detection problems is to detect the change point “as soon as possible” but avoiding too many false alarms. We distinguish discrete-time and continuous-time models.

Discrete-Time Models

In the discrete case, let $X_1, X_2, \dots$ be a sequence of independent random variables which are observed sequentially. The first $X_1, \dots, X_{\theta-1}$, $\theta > 1$ are distributed according to some known distribution F_0 , while $X_\theta, X_{\theta+1}, \dots$ have some known distribution function $F_1 \neq F_0$. The change point θ is unknown. The time of alarm (a change point has occurred) is determined by a stopping rule which takes the random observations into account. Concerning the change point, there exist Bayesian and non-Bayesian approaches. One of the first non-Bayesian methods is the **CUSUM**-procedure proposed by Page [5], which was further investigated by Lorden [6] and Moustakides [7].

A Bayesian formalization of the disorder problem goes back to Shiryaev [8]. He postulated that the change point θ has a geometric *a priori* distribution with some parameter p and considered the following risk function $R(\tau)$ for stopping at τ : $R(\tau) = P(\tau < \theta) + cE(\tau - \theta)^+$. Here the penalty costs of a false alarm are normalized to 1, and the costs for the delay of stopping after the change point are c per unit time. Now the Bayes stopping rule is to stop at the smallest n for which the posterior probability $\Pi_n = P(\theta \leq n | X_1, \dots, X_n)$ of a change up to n is greater than some threshold A for some $0 < A < 1$.

Continuous-Time Model

Shiryaev [8] was also one of the first to present a model in continuous time in a Bayesian framework:

2 Change-Point Models

the change point is assumed to be a random variable with some prior distribution. Shiryaev considered the following observation process

$$W_t = B_t + r(t - \theta)^+, \quad t \in [0, \infty) \quad (1)$$

where B denotes a standard **Brownian motion**, r is a known fixed constant, and θ is an unknown (random) change point, which is assumed to be independent of B and to have a mixed exponential prior distribution: $P(\theta = 0) = p$ and $P(\theta > t) = (1 - p)e^{-\lambda t}$, $p \in [0, 1)$, $\lambda > 0$, $t \geq 0$. The stopping time τ with respect to the filtration generated by W should signal the change in the drift as soon as possible. The speed of detection is measured by the risk function $R(\tau)$, which is the same as in the discrete-time case. A Bayes solution τ^* should minimize the risk

$$R(\tau^*) = \inf_{\tau} R(\tau) \quad (2)$$

The optimal stopping time τ^* can be determined by means of the posterior distribution $\Pi_t = P(\theta \leq t | \mathcal{F}_t^W)$, with $\mathcal{F}_t^W = \sigma\{W_s : s \leq t\}$. Then the optimal stopping time is

$$\tau^* = \inf\{t > 0 | \Pi_t \geq p^*\} \quad (3)$$

for some properly chosen $p^* \in [0, 1)$. Details about this approach can be found in [9]. An explicit expression for the optimal threshold p^* , and further ramifications can be found in [10, 11].

Another type of change-point problem has been studied in recent years, namely the Poisson disorder problem. Instead of considering a Wiener process with changing drift, a **Poisson process** with changing intensity is observed. Then the problem is to determine a stopping time that signals a change of the intensity of the observed Poisson process. Formally, a point process (T_n) , $n \in \mathbb{N}$ and its corresponding counting process $N_t = \sum_{n=1}^{\infty} I_{\{T_n \leq t\}}$ are observed, where I is the indicator function. At an unknown random time θ , the intensity of N switches from μ_0 to $\mu_1 > \mu_0$. This means that if θ is given, N is a Poisson process with intensity μ_0 up to θ and a Poisson process with intensity μ_1 after θ . [12] described the structure of the solution in the general case. They assumed that θ is a random variable independent of the Poisson process having a mixed exponential prior distribution with parameters p and λ as before. The objective is to stop as soon as possible after θ . The associated risk function

$R(\tau) = P(\tau < \theta) + cE(\tau - \theta)^+$ is given as before and the optimal stopping time in the case $\mu_1 > \mu_0$ is $\tau^* = \inf\{t \geq 0 | \Pi_t \geq B^*\}$, where

$$B^* = \begin{cases} \frac{\lambda}{\lambda + c}, & c \geq \mu_1 - \mu_0 - \lambda \\ \frac{\lambda(\mu_1 - c)}{\lambda\mu_1 + c\mu_0}, & \mu^* \leq c < \mu_1 - \mu_0 - \lambda \end{cases} \quad (4)$$

is the optimal stopping threshold and $\mu^* = \mu_0\mu_1(\mu_0 - \mu_1 - \lambda)/\mu_0\mu_1 + (\mu_1 - \mu_0)(\lambda + \mu_0)$ and (Π_t) , $t > 0$ is the posterior probability process $\Pi_t = P(\theta \leq t | \mathcal{F}_t^N)$, with respect to the filtration $\mathcal{F}_t^N = \sigma\{N_s : s \leq t\}$ and the prior distribution. This stopping time τ^* is obtained by the use of the same methodology as in the Wiener process case. Brown and Zacks [13] extended this result for $\mu^* > c$ using dynamic programming.

A different approach was made by Herberts and Jensen [14]. They solved the detection problem by deriving a semimartingale representation of a gain process whose expectation corresponds to the risk process. In a Bayesian framework, the change point has an exponential prior with parameter λ . The gain process, considered by Herberts and Jensen [14] is a generalization of the one introduced by Shiryaev and is given by

$$Z_t = c_0 \min(t, \theta) + c_1(t - \theta)^+ - k_0(1 - I_{\{\theta \leq t\}}) - k_1 I_{\{\theta \leq t\}} \quad (5)$$

if the process is stopped at time t . There is a gain of c_0 per unit of time and costs k_0 for stopping the process before the change occurs, and a gain c_1 per unit time and stopping costs k_1 afterward. The problem of detecting the change point is then formulated as an optimal stopping problem: find a stopping time ζ with respect to the given observation filtration $\mathbb{F}$ such that $EZ_{\zeta} = \sup_{\tau} \{EZ_{\tau} : \tau \in C^{\mathbb{F}}\}$ where (Z_t) , $t \in \mathbb{R}_+$ is the gain process and $C^{\mathbb{F}}$ is the set of admissible stopping times. Their method goes beyond classical approaches, particularly because it can be used for different information schemes, that is for sequentially observed data, *ex post* decision after observing the point process up to a fixed time t^* , and a combination of both observation schemes. In the sequential case, the observation filtration $\mathbb{F} = (\mathcal{F}_t)$ is the point process history $\mathcal{F}_t = \mathcal{F}_t^N$. In the *ex post* case, the history of N is always known for the whole observation period up to t^* ; therefore, we have in this case $\mathcal{F}_t = \mathcal{F}_{t^*}^N$ for all t , $0 \leq t \leq t^*$. In both cases, the

optimal stopping time can be determined explicitly. In the case of sequential observation, it is given by

$$\zeta^{\mathbb{F}^N} = \inf\{t \in \mathbb{R}_+ : \widehat{Y}_t^{\mathbb{F}^N} \geq z^*\} \quad (6)$$

where $\widehat{Y}_t^{\mathbb{F}^N} = P(\theta \leq t | \mathcal{F}_t^N)$ can be calculated explicitly and $z^* = c_0 + \lambda(k_0 - k_1)/c_0 - c_1 + \lambda(k_0 - k_1)$. In the *ex post* case the solution is a bit more complex and can be found, among other details and more references, in [14].

In recent years, not only homogeneous but also inhomogeneous Poisson process models have been studied. We refer to [15] and [16].

Change Points in Regression and Hazard Rate Models

Regression Models

In the literature two different types of change-point regression models can be found: on the one hand, so-called time-varying regression models, in which the model parameters change at some unknown point in time, and on the other hand, two-phase regression models. Both models are presented briefly in the following.

In the time-varying model, a change in the regression coefficients takes place from the early to the late observations of a sequence (X_n) , $n \in \mathbb{N}$. Let $(X_1, Y_1), \dots, (X_n, Y_n)$ be independent random vectors. Then the model in the random design is given by

$$Y_i = \begin{cases} \alpha_0 + \alpha_1 X_i + \epsilon_i, & i \leq \tau \\ \beta_0 + \beta_1 X_i + \epsilon_i, & i \geq \tau + 1 \end{cases} \quad (7)$$

where (X_i) and (ϵ_i) , $i = 1, \dots, n$ are mutually independent, independent and identically distributed (i.i.d.) sequences with $E(\epsilon_i) = 0$ and $E(\epsilon_i^2) = 1$ and $(\alpha_0, \alpha_1) \neq (\beta_0, \beta_1)$. If $1 \leq \tau \leq n - 1$, then τ is a change point. This design is called *fixed*, if the sequence (X_i) , $i = 1, \dots, n$ is nonstochastic. A two-phase regression model is a regression model with piecewise linear regression functions over two different domains of the design variable. The random design of a two-phase regression model is given by

$$\begin{aligned} Y_i &= (\alpha_0 + \alpha_1 X_i)I_{\{X_i \leq \tau\}} + (\beta_0 + \beta_1 X_i)I_{\{X_i > \tau\}} + \epsilon_i \\ &= m(X_i) + \epsilon_i \end{aligned} \quad (8)$$

The two-phase regression models can be classified further into a restricted and an unrestricted case.

In the restricted case, the regression function f is continuous but not differentiable, whereas in the unrestricted case the regression function is discontinuous. The discontinuity can be expressed in the form of a fixed jump size or a contiguous jump size, in which the jump size tends to zero as the **sample size** tends to infinity.

Hinkley [17] was one of the first authors to investigate a maximum-likelihood estimator (MLE) of the point of intersection for the special case of two line segments under normally distributed errors. A generalization of his model with multiple change points was considered by Feder [18, 19], who investigated least-squares estimates and showed that these estimates are consistent under suitable identifiability assumptions and the asymptotic distributions of these estimates are obtained by “classical” methods.

Koul and Qian [20] and Koul *et al.* [21] considered M-estimators in the unrestricted two-phase random design with a fixed jump size. The M-process corresponding to a function $\phi : \mathbb{R} \rightarrow [0, \infty)$ is defined as

$$M_n(\theta) = \sum_{i=1}^n \phi(Y_i - m(X_i, \theta)) \quad (9)$$

where $m(X; \theta)$ is the linear regression function of model (8) and the M-estimator $\widehat{\theta}$ is given as the minimizer of the M-process:

$$M_n(\widehat{\theta}) = \inf_{\theta} M_n(\theta) \quad a.s. \bullet \quad (10)$$

They showed that the estimate of the jump point converges with rate $O_p(n^{-1})$, whereas the consistency rate of the coefficient parameters is $O_p(n^{-1/2})$. The normalized M-process is asymptotically equivalent to the sum of two processes. One is a quadratic form in the standardized coefficient parameter vector, the other is a jump-point process in the change-point parameter. This result can be exploited to show weak convergence. The suitably standardized M-estimator of the change point converges weakly to the minimizer of a compound Poisson process. The estimates of the regression coefficients are asymptotically normal and independent of the jump-point M-estimator. This is remarkable because the results differ from the restricted and unrestricted contiguous nonrandom design cases.

All models considered above assumed a parametric setting. Of course, there exist various nonparametric

4 Change-Point Models

models as well. Müller [22] studied the following fixed-design nonparametric regression model

$$Y_{in} = g(t_{in}) + \epsilon_{in}, \quad t_{in} \in [0, 1], \quad 1 \leq i \leq n \quad (11)$$

where Y_{in} are noisy measurements of the regression function g taken at points t_{in} and $\epsilon_{in} \sim \mathcal{N}(0, \sigma^2)$ are i.i.d. errors. The assumption is made that there is a change point for the v th derivative $g^{(v)}$ at τ , $0 < \tau < 1$ in the following sense: there exists a function $f \in \mathcal{C}^{k+v}([0, 1])$ with $v \geq 0$ and $k \geq 2$ an even integer, such that

$$g^{(v)}(t) = f^{(v)}(t) + \Delta_v I_{[\tau, 1]}(t), \quad \Delta_v > 0, \quad 0 \leq t \leq 1 \quad (12)$$

The case $\Delta_v < 0$ can be treated analogously. Now, the jump size at the possible change point τ of the v th derivative of g is given by

$$\Delta_v = g_+^{(v)}(\tau) - g_-^{(v)}(\tau) \quad (13)$$

where $g_+^{(v)}(x) = \lim_{y \downarrow x} g^{(v)}(y)$ and $g_-^{(v)}(x) = \lim_{y \uparrow x} g^{(v)}(y)$ are the one-sided limits of the derivative $g^{(v)}(x)$. Hence, the idea is to base the inference of the change points on differences between the left- and right-sided estimates of $g^{(v)}(t)$, which can be done by suitably chosen one-sided kernel estimates. The location of the maximum of these differences is a reasonable estimator of the location of the change point. Let τ be an element of a closed interval $T \subset (0, 1)$. Then the estimator is

$$\hat{\tau} = \inf\{\rho \in T : \hat{\Delta}_v(\rho) = \sup_{x \in T} \hat{\Delta}_v(x)\} \quad (14)$$

In this setting, Müller [22] proved weak convergence of the estimator $\hat{\tau}$. Loader [23] considered a similar nonparametric regression model in which the mean function may have a discontinuity at an unknown point. His estimate is similar in principle to that studied by Müller [22]. However, since he imposed different conditions on the kernel K , his estimate has different properties. It is shown that the change-point estimate converges in probability with rate $O_p(n^{-1})$ and that it has the same asymptotic distribution as maximum-likelihood estimates in parametric models.

The same convergence rate is attained by Müller and Song [24] in a two-step **estimation** of the change point in a nonparametric fixed-design regression model with fixed jump size, whereas the convergence rate in the contiguous case is $O_p(n^{-1} \Delta_n^{-2})$, where

Δ_n is a sequence of jump sizes which tends to zero.

Another important problem in modeling data is the question of whether an unknown function, which cannot parametrically be specified, should be modeled as a globally smooth function or a smooth function with isolated change points. Müller and Stadtmüller [25] proposed statistics, which provide relevant information for this decision.

Hazard Rate Models

Hazard rate models often occur in medical follow-up studies after major surgery. The simplest one with a change point can be expressed as follows

$$\lambda(t) = \begin{cases} \lambda_1 & t \leq \tau \\ \lambda_2 & t > \tau \end{cases}, \quad t \geq 0, \quad \tau \geq 0 \quad (15)$$

with constants $\lambda_1, \lambda_2 > 0$ and change point τ . A first attempt to estimate these three parameters was made by Anderson and Senthilselvan [26]. They investigated, as a special case of this simple model, an extended **Cox model** with $\lambda_1 = e^{\alpha^T Z}$, $\lambda_2 = e^{\gamma^T Z}$, where α and γ are parameter vectors and Z is a vector of covariates. The parameters are estimated by the conditional log likelihood given the value of τ and then the baseline hazard $\lambda(t)$ is estimated by a penalized maximum-likelihood method conditioning on the parameter estimates. Liang *et al.* [27] proposed a slightly different Cox model

$$\lambda(t) = \lambda_0(t) \exp\{(\beta + \theta I_{[t \leq \tau]})Z + \gamma^T X\} \quad (16)$$

where Z is a one-dimensional **covariate** which should be included in possibly different magnitudes over time, X is another confounding covariate vector and the change point at an unknown time is given by τ . They tested the hypothesis of $H_0 : \theta = 0$ using a test statistic

$$M = \sup_{\tau \in [a, b]} S(\tau) \quad (17)$$

where S is a function of the first two derivatives of the partial log-likelihood function with respect to β and γ .

A further Cox model is presented by Luo and Boyett [28]:

$$\lambda(t) = \lambda_0(t) \exp\{\beta I_{[X \leq \theta]} + \alpha^T Z\} \quad (18)$$

where a constant is added to a covariate beyond a threshold, which is characterized by a random variable X . They proved consistency of their partial MLE.

A Cox model for i.i.d. censored survival times with a change point according to the unknown threshold of a covariate was introduced by Pons [29]:

$$\lambda(t) = \lambda_0(t) \exp\{\alpha^T \mathbf{Z}_1(t) + \beta^T \mathbf{Z}_2(t) I_{\{Z_3 \leq \zeta\}} + \gamma^T \mathbf{Z}_2(t) I_{\{Z_3 > \zeta\}}\} \quad (19)$$

In this model, it is shown that the partial MLE of the change point ζ is n consistent, i.e. the convergence rate is $O_p(n^{-1})$. Such a convergence rate was also attained for the change point in the unrestricted two-phase random linear regression design with a fixed jump size (see [20]). Furthermore, Pons [29] proved that the estimates of the regression parameter vectors α, β, γ are $n^{1/2}$ consistent and that $n(\hat{\zeta}_n - \zeta)$ converges weakly to a random variable $\hat{v}_Q$, which is a maximizer of a certain jump process. The estimates of the regression parameters are asymptotically normal.

Gandy *et al.* [30] investigated a similar model. But instead of a jump there is a smooth change at the change point ξ :

$$\lambda_i(t, \theta) = \lambda_0(t) R_i(t) \exp\{\beta_1^T \mathbf{Z}_{1i}(t) + \beta_2 Z_{2i} + \beta_3 (Z_{2i} - \xi)^+\} \quad (20)$$

where $\theta = (\xi, \beta^T)^T$ with $\beta = (\beta_1^T, \beta_2, \beta_3)^T \in \mathcal{B} \subset \mathbb{R}^{p+2}$ is the vector of regression parameters and R_i the at-risk indicator. The change point is denoted by ξ lying in a closed interval of known parameters $[\xi_1, \xi_2]$. For brevity, $\tilde{\mathbf{Z}}_i(t; \xi) = (\mathbf{Z}_{1i}^T(t), Z_{2i}, (Z_{2i} - \xi)^+)^T$ is considered resulting in $\lambda_i(t, \theta) = \lambda_0(t) R_i(t) \exp\{\beta^T \tilde{\mathbf{Z}}_i(t; \xi)\}$. In this new, extended Cox model θ is estimated by the value $\hat{\theta}_n$ that maximizes the logarithm of the partial likelihood:

$$\begin{aligned} \log L(\theta) = & \sum_{i=1}^n \int_0^\tau \beta^T \tilde{\mathbf{Z}}_i(t; \xi) dN_i(t) \\ & - \int_0^\tau \log \left(\sum_{i=1}^n R_i(t) \exp(\beta^T \tilde{\mathbf{Z}}_i(t; \xi)) \right) \\ & \times d \left(\sum_{i=1}^n N_i(t) \right) \end{aligned} \quad (21)$$

The maximization can be carried out in the following way:

For fixed ξ , let $\hat{\beta}_n(\xi) = \arg\max_{\beta \in \mathcal{B}} \log L(\xi, \beta)$ and $\log L(\hat{\xi}) = \log L(\hat{\xi}, \hat{\beta}_n(\hat{\xi}))$. Then $\hat{\xi}$ can be estimated by $\hat{\xi}_n$ satisfying

$$\hat{\xi}_n = \inf \left\{ \xi \in [\xi_1, \xi_2] : \log L(\xi) = \sup_{\xi \in [\xi_1, \xi_2]} \log L(\xi) \right\} \quad (22)$$

The partial MLE of θ is $\hat{\theta}_n = (\hat{\xi}_n, \hat{\beta}_n)$, where $\hat{\beta}_n = \hat{\beta}_n(\hat{\xi}_n)$.

It is proved that the partial MLE of all parameters is $n^{1/2}$ consistent. In contrast to Pons' model $n^{1/2}(\hat{\xi} - \xi_0)$ is asymptotically normal. The proof uses results of the theory of M -estimators as presented in [31]. The model can be extended further by substituting a vector $\mathbf{Z}_2$ for Z_2 , which may also be time dependent, and a vector ξ for ξ allowing more than just one change point. The asymptotic results are still the same.

Other approaches relying on the Cox model have recently been suggested by Dupuy [32]. He considered a model with a change point in both hazard and regression parameters. Estimates of the change point, hazard, and regression parameters are proposed and shown to be consistent.

System Signatures

Introduction

Structural reliability is a subfield of reliability theory which is concerned with the precise way in which systems are designed, that is, the way that the system's components work individually, and in tandem with others, to make the system itself function or fail. In a seminal paper in the field, Birnbaum *et al.* [1] defined a coherent system as one which is monotonic (i.e., fixing a failed component cannot cause a system to fail) and in which every component is relevant (i.e., for every i , there's at least one configuration of component states in which the i^{th} component's failure will make the system fail). They argued persuasively that these were the only systems meriting further study, as any incoherent system could be replaced by a coherent system of the same or smaller size having performance characteristics as good as or better than the original system.

For a system with n components, Birnbaum *et al.* [1] defined the state vector $\mathbf{x} = (x_1, x_2, \dots, x_n) \in \{0, 1\}^n$ of the system's components as the vector of 0s and 1s such that $x_i = 1$ if the i^{th} component is working and $x_i = 0$ if it is not working. The structure function $\varphi : \{0, 1\}^n \rightarrow \{0, 1\}$ of a given system is then defined as a mapping that associates those state vectors $\mathbf{x}$ for which the system works with the value 1 and those state vectors $\mathbf{x}$ for which the system fails with the value 0.

These two ideas – coherence and structure – form the foundation of modern structural reliability and, at least in theory, allow one to study the performance of a given system and to compare any pair of systems of interest. They lead, for example, to the calculation of the reliability $h(\mathbf{p})$ of a system in independent components for which $P(X_i = 1) = p_i$ for $i = 1, 2, \dots, n$; specifically, $h(\mathbf{p}) = E\varphi(\mathbf{X})$. The reliability function $h(\mathbf{p})$ is multilinear, that is, linear in each p_i , and when $p_i \equiv p$ for all i , a case of special interest, it can be written as the n^{th} degree polynomial referred to as the *reliability polynomial* for the system. For further detail on these ideas and their consequences, see Barlow and Proschan [2].

While the ideas discussed above are without doubt two of the more important conceptual breakthroughs in the mathematical theory of reliability, as tools for the computation of system reliability and for

the comparative study of different system designs, they have a number of limitations. As informative as structure functions are in determining how systems work, the class has the same cardinality as the class of **coherent systems** themselves and so their number grows exponentially in n . Further, they are complex algebraic expressions that usually have many equivalent forms. It is thus awkward, and often unfeasible, to use them as a way of indexing and/or comparing systems. In a 1985 paper, Samaniego introduced an alternative index which, although less general than structure functions, has the virtues of being both quite useful and easily interpreted. For systems of order n , this index is of fixed dimension; in fact, it resides in a bounded simplex in n -dimensional Euclidean space. This index, called the *system's signature*, is defined as follows.

Definition 1 Let τ represent a coherent system of order n . Assume that the system's n components are independent and identically distributed (i.i.d) according to the (continuous) lifetime distribution F . The *signature* of the system τ , denoted by $\mathbf{s}_\tau$, or simply by $\mathbf{s}$ when the corresponding system is clear from the context, is an n -dimensional probability vector whose i^{th} element s_i is equal to the probability that the i^{th} component failure causes the system to fail. In brief, $s_i = P(T = \mathbf{X}_{i:n})$ for $i = 1, 2, \dots, n$, where T is the lifetime distribution of the system and $\mathbf{X}_{1:n} < \mathbf{X}_{2:n} < \dots < \mathbf{X}_{n:n}$ are the ordered failure times of the system's n components.

Some comments on the i.i.d. assumption on component lifetimes would seem to be in order. The primary use of signatures to date has been the comparison of system designs. It is quite apparent that a comparison between two systems with quite different component characteristics may well be misleading or inconclusive. For example, a series system in four highly reliable components is likely to outperform a four-component parallel system with relatively poor components. But it's clear that **parallel systems** are preferable to **series systems** of the same order. Indeed, the two systems' structure functions are uniformly ordered in $\mathbf{x}$. On the other hand, once the i.i.d. assumption is made, any remaining differences in system performance must be attributable to the system's design. In that sense, the assumption levels the playing field so that one has a basis for comparing the designs themselves. From an analytical

2 System Signatures

point of view, signatures, as defined above, make available for use the tools of combinatorial mathematics for computational purposes and the well-known distribution theory for the order statistics of an i.i.d. sample for studying the performance of a particular system. It should, of course, be acknowledged that specific applications of signature-related results in non-i.i.d. settings must be done, if at all, with caution. This caveat notwithstanding, it is also worth adding that results based on an i.i.d. assumption, while being inexact in such applications, are not necessarily irrelevant. If, for example, the component lifetimes could be considered independent and, while not identically distributed, nonetheless roughly comparable, it seems reasonable to conclude from the results cited in the sequel that selecting the system with a better signature should lead to better performance. Naturally, an exact analysis is desirable, but it will often be intractable. The signature-related results to be discussed here should be of some use in some ‘neighborhood’ of the i.i.d. setting that has been studied via system signatures.

The following simple example illustrates the type of reasoning which proves useful in the computation of system signatures. Consider the system pictured in Figure 1 below. The failure times $\mathbf{X}_1$, $\mathbf{X}_2$, and $\mathbf{X}_3$ of the three components of this system can be ordered in $3! = 6$ ways, and these six possible permutations are equally likely due to the i.i.d. assumption. The ‘order-statistic equivalent’ for the system failure time T is shown in Table 1 below for each permutation of the component failure times.

Clearly, the system in Figure 1 has signature vector $\mathbf{s} = (1/3, 2/3, 0)$. Note that in this example, and in general, the signature of a system depends only on the permutation distribution of the n failure times and does not depend in any way on the continuous lifetime distribution F . The five distinct coherent systems of order 3 are easily seen to have signatures $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$, $(1/3, 2/3, 0)$, and $(0, 2/3, 1/3)$.

Figure 1 A three-component system with structure function $\varphi^*(\mathbf{x}) = x_1(x_2 + x_3 - x_2x_3)$

Table 1 The ordered component failure time which causes failure of system φ^* above

Ordered component failure times	Order statistic equal to system failure time T
$\mathbf{X}_1 < \mathbf{X}_2 < \mathbf{X}_3$	$\mathbf{X}_{1:3}$
$\mathbf{X}_1 < \mathbf{X}_3 < \mathbf{X}_2$	$\mathbf{X}_{1:3}$
$\mathbf{X}_2 < \mathbf{X}_1 < \mathbf{X}_3$	$\mathbf{X}_{2:3}$
$\mathbf{X}_2 < \mathbf{X}_3 < \mathbf{X}_1$	$\mathbf{X}_{2:3}$
$\mathbf{X}_3 < \mathbf{X}_1 < \mathbf{X}_2$	$\mathbf{X}_{2:3}$
$\mathbf{X}_3 < \mathbf{X}_2 < \mathbf{X}_1$	$\mathbf{X}_{2:3}$

Signature-Based Representations

Samaniego [3] showed that the distribution of the system lifetime T , given i.i.d. components lifetimes $\sim F$, can be written in terms of $\mathbf{s}$ and F alone:

Theorem 1 Let $\mathbf{X}_1, \dots, \mathbf{X}_n$ be the i.i.d. component lifetimes of a coherent system of order n , and let T be the system lifetime. Then

$$\bar{F}_T(t) \equiv P(T > t) = \sum_{j=0}^{n-1} \left(\sum_{i=j+1}^n s_i \right) \binom{n}{j} \times (F(t))^j (\bar{F}(t))^{n-j} \quad (1)$$

Assuming i.i.d components and letting t_0 be a fixed point in time, set $p = \bar{F}(t_0)$ and $q = F(t_0)$. The reliability of the system at $t = t_0$, or equivalently, the reliability polynomial $h(p)$, may then be written as

$$h(p) = \sum_{j=1}^n \left(\sum_{i=n-j+1}^n s_i \right) \binom{n}{j} p^j q^{n-j} \quad (2)$$

It is evident from the representation in (1) that the survival function of T can also be written as

$$P(T > t) = \sum_{i=1}^n s_i P(\mathbf{X}_{i:n} > t) \quad (3)$$

Integrating both sides of equation (3) over $t \in (0, \infty)$, we obtain the useful identity

$$ET = \sum_{i=1}^n s_i E\mathbf{X}_{i:n} \quad (4)$$

Samaniego [3] also established the following representations for the density and failure rate of T when

F is absolutely continuous:

$$f_T(t) = \sum_{i=1}^n i s_i \binom{n}{i} (F(t))^{i-1} (\bar{F}(t))^{n-i} f(t) \quad (5)$$

and

$$r_T(t) = \frac{\sum_{i=1}^n i s_i \binom{n}{i} (F(t))^{i-1} (\bar{F}(t))^{n-i+1}}{\sum_{i=1}^n s_i \sum_{j=0}^{i-1} \binom{n}{j} (F(t))^j (\bar{F}(t))^{n-j}} r(t) \quad (6)$$

where f and r are the density and failure rate of the underlying distribution F .

The following is a brief overview of some of the main applications to date of signatures in reliability. The first of these results shows that certain stochastic relationships enjoyed by pairs of system signatures are preserved by the lifetimes of the corresponding systems. For definitions of stochastic, hazard rate and likelihood ratio ordering between random variables (or their distributions), see Shaked and Shanthikumar [4]. In the following result, due to Kochar *et al.* [5], signatures are seen as the distributions of discrete variables taking values in $\{1, 2, \dots, n\}$.

System Comparisons

Theorem 2 Let $\mathbf{s}_1$ and $\mathbf{s}_2$ be the signatures of the two systems of order n , both based on components with i.i.d. lifetimes with common distribution F . Let T_1 and T_2 be the respective system lifetimes. Then (a) $\mathbf{s}_1 \leq_{\text{st}} \mathbf{s}_2 \Rightarrow T_1 \leq_{\text{st}} T_2$, (b) $\mathbf{s}_1 \leq_{\text{hr}} \mathbf{s}_2 \Rightarrow T_1 \leq_{\text{hr}} T_2$, and (c) $\mathbf{s}_1 \leq_{\text{lr}} \mathbf{s}_2 \Rightarrow T_1 \leq_{\text{lr}} T_2$.

Block *et al.* [6] noted that the signature conditions in Theorem 2 are sufficient but not necessary, and generalized the result, giving explicit necessary and sufficient conditions (NASCs) for $T_1 \leq T_2$ in each of the three stochastic senses considered above.

While stochastic relationships between signatures are clearly useful tools in the comparison of competing systems, they provide only a partial ordering among systems. Kochar *et al.* [5] give examples of systems that are noncomparable according to the standard orderings. There is, however, a metric under which any two systems are comparable. Arcones *et al.* [7] introduced the notion of ‘stochastic

precedence’, an alternative way to quantify the fact that one random variable is smaller than another. They defined the ‘sp’ relationship as follows.

Definition 2 Let Y_1 and Y_2 be independent random variables with respective distributions F_1 and F_2 . Then Y_1 is said to *stochastically precede* Y_2 (written $Y_1 \leq_{\text{sp}} Y_2$) if and only if $P(Y_1 \leq Y_2) \geq 1/2$. The variables are *equivalent* if both $Y_1 \leq_{\text{sp}} Y_2$ and $Y_2 \leq_{\text{sp}} Y_1$ hold. Continuous variables Y_1 and Y_2 are sp-equivalent if and only if $P(Y_1 \leq Y_2) = 1/2$.

Hollander and Samaniego [8] consider the comparison of T_1 and T_2 via stochastic precedence. As we shall see, $P(T_1 \leq T_2)$ can be computed in closed form under an i.i.d. assumption, and one may then classify the second system as better than, equivalent to or worse than the first system according to whether $P(T_1 \leq T_2)$ is greater than, equal to or less than $1/2$. It is therefore apparent that any two systems of arbitrary order are comparable via stochastic precedence. Below, an explicit formula for calculating the probability $P(T_1 \leq T_2)$ when all components have i.i.d. lifetimes with continuous distribution F . Hollander and Samaniego [8] establish the following results.

Theorem 3 Consider coherent systems τ_1 and τ_2 of orders n and m respectively, and assume that their component lifetimes are i.i.d. according to continuous distributions F_1 and F_2 , respectively. Let $\mathbf{s}_1$ and $\mathbf{s}_2$ be their signatures and T_1 and T_2 be their lifetimes. Then

$$P(T_1 \leq T_2) = \sum_{i=1}^n \sum_{j=1}^m s_{1i} s_{2j} P(\mathbf{X}_{i:n} \leq \mathbf{Y}_{j:m}) \quad (7)$$

The following computational formula for $P(T_1 \leq T_2)$, applicable when $F_1 = F_2$, follows from the explicit formula obtained by Kvam and Samaniego [9] for the probability of a given ordering among independently drawn order statistics.

Theorem 4 Under the conditions of Theorem 3, and given that $F_1 = F_2$,

$$P(T_1 \leq T_2) = \sum_{i=1}^n \sum_{j=1}^m s_{1i} s_{2j} \sum_{k=i}^n \left[\frac{\binom{n}{k} \binom{m}{j}}{\binom{n+m}{k+j}} \right] \times \left[\frac{j}{(k+j)} \right] \quad (8)$$

Example It is easy to verify that the two four-component systems with respective minimal cut sets $\{\{1\}, \{2, 3, 4\}\}$ and $\{\{1, 2\}, \{1, 3\}, \{1, 4\}, \{2, 3\}\}$ are noncomparable in the ‘st’ sense (or, of course, also in the ‘hr’ or ‘lr’ senses). The first of these systems has signature $\mathbf{s}_1 = (1/4, 1/4, 1/2, 0)$ and the second has signature $\mathbf{s}_2 = (0, 2/3, 1/3, 0)$. Assuming that all components are i.i.d. $\sim F$, one obtains from equation (8) that $P(T_1 \leq T_2) = 0.519$. From this one may conclude that the second system will last longer than the first, slightly more than half the time. Thus, in the ‘sp’ ordering, the second system is to be preferred to the first.

The expression in (8) is clearly distribution free, immediately yielding NASCs for stochastic precedence between two systems of arbitrary order with i.i.d. component lifetimes. Indeed, if the RHS of equation (8) is denoted by $W(\mathbf{s}_1, \mathbf{s}_2)$, then

$$P(T_1 \leq T_2) > \frac{1}{2} \left(\text{or} = \frac{1}{2} \text{ or } < \frac{1}{2} \right) \text{ if and only if} \\ W(\mathbf{s}_1, \mathbf{s}_2) > \frac{1}{2} \left(\text{or} = \frac{1}{2} \text{ or } < \frac{1}{2} \right) \quad (9)$$

Related Literature

There are a variety of further applications of system signatures which merit discussion. The following is a brief summary. Using the representation of the system failure rate in equation (6), Samaniego [3] provides a characterization, in terms of system signatures, of systems whose lifetime distributions have an increasing failure rate whenever their components have i.i.d. lifetimes with an increasing failure rate. Boland [10] derives the signatures of indirect majority systems and executes a comparison of such systems with simple majority systems of the same size. Shaked and Suarez-Llorens [11] use conditions on system signatures to obtain comparisons of systems *via* the information and the dispersive orderings. Belzunce and Shaked [12] obtain results for pairs of signatures with specific relationships *via* their theory of failure profiles. Navarro and Shaked [13] utilize signatures in showing hazard-rate ordering among independently drawn minima $\{\mathbf{X}_{1:1}, \mathbf{X}_{1:2}, \dots, \mathbf{X}_{1:n}, \dots\}$ and in studying the limiting behavior of the failure rates of selected systems. Dugas and Samaniego [14] study optimization problems in reliability economics

and identify optimal designs (i.e., optimal stochastic mixtures of coherent systems) relative to a class of criterion functions of the form $m(\bar{a}, \bar{c}, \bar{s})$, where $\bar{a}$ is a measure of the system’s performance, $\bar{c}$ is a measure of the system’s cost and $\bar{s}$ is the system’s signature.

Satyanarayana and Prabhakar [15] introduced an important computational approach called *domination theory* aimed at simplifying the use of the inclusion-exclusion formula in the computation of the reliability of complex communication networks. While this tool has been a substantial boon computationally, the method does not appear to have any clear interpretive content. For a coherent system in i.i.d. components, it provides an efficient way to obtain the reliability polynomial

$$h(\mathbf{p}) = \sum_{j=1}^n d_j p^j \quad (10)$$

where $\mathbf{d} = (d_1, d_2, \dots, d_n)$ is the vector of ‘signed dominations’. Boland *et al.* [16] explicitly identify the relationship between the domination and signature vectors in the form $\mathbf{s} = \mathbf{Q}\mathbf{d}$, where $\mathbf{Q}$ is a specific $n \times n$ matrix (thereby reconciling equations (2) and (10)). They illustrate the correspondence and joint utility of $\mathbf{s}$ and $\mathbf{d}$ by demonstrating that the lifetimes of two complex networks (both with 9 vertices and 27 edges) are hazard-rate ordered. The work facilitates the concurrent use of dominations for reliability computation and signatures for comparative analysis of systems or networks.

Details on much of the work described in this article can be found in the cited references, and in particular, in the monograph by Samaniego [17].

Bayesian Reliability Demonstration

Introduction

Many systems are required to be highly reliable, and prior to their practical use such reliability may need to be demonstrated through testing. This requires determination of the amount and type of testing that is needed in order to demonstrate a certain level of reliability. In many situations, in particular where high reliability is required, one would not accept faults occurring during such testing, as these are evidence against the system's ability to perform its task well and are likely to lead to rejection of the system. As such reliability demonstration testing clearly deals with uncertainty and information to reduce this uncertainty, statistical methods can provide valuable insights and can guide such testing. We focus on **Bayesian methods**, which allow previous information to be taken into account in a subjective manner *via* the prior distribution chosen, and, as such, can lead to reduced test effort. However, when emphasizing the *demonstration* of reliability, it might not be considered appropriate to rely on prior information, be it based on historical data from similar systems or expert judgement. We will discuss this feature in detail, as it strongly influences the choice of prior distribution. But first, we provide a brief overview of some key contributions to the literature on Bayesian reliability demonstration (BRD), and we focus on the criterion used for "reliability".

In line with the increasing development and popularity of Bayesian statistical inference in the late 1960s and 1970s, many researchers in reliability developed BRD test philosophies and procedures during this period. An excellent overview of contributions to BRD during this period is given in Chapter 10 of Martz and Waller's well-known book *Bayesian Reliability Analysis* [1]. A key topic is the choice of BRD criterion. Traditionally [1], criteria considered were closely linked to those in related statistical areas such as **quality control**, and mostly used producer's and consumer's risks expressed in terms of acceptance or rejection of a system after BRD testing, conditional on assumptions on characteristics of the system's failure distribution. Here, we use "failure distribution" as a generic term for the

probability distribution of the random variables of interest in BRD, which might, for example, include number of failures over defined periods of testing (as is typical in so-called "attribute testing") or times between failures. The characteristics typically used are a parameter representing the proportion of failures, as a population characteristic in the standard statistical sense for Bernoulli random quantities (attribute testing) or **Mean-Time-To-Failure** (MTTF) or **Mean-Time-Between-Failures** (MTBF). It is important to notice that, although such characteristics have intuitive appeal, they are not directly observable and only meaningful in combination with additional statistical modeling assumptions (mostly exchangeability of the random quantities of interest). The Bayesian approach to reliability demonstration distinguishes itself from other statistical approaches to such problems *via* the use of **prior distributions** on these parameters, which can reflect prior knowledge – a crucial question is, of course, whether or not such prior knowledge should be included in BRD and, if perhaps not, what role the Bayesian prior then might have and how it can be chosen (we return to this important issue in the section titled "The Prior Distribution"). Once one accepts the more or less traditional framework for **sample size** determination *via* producer's and consumer's risks, a variety of probabilities can be considered for the detailed specification of the BRD criterion, and all of these lead to many different solutions, which are however closely related from philosophical perspectives. Such probabilities include posterior risks, average risks and rejection probabilities, and study of corresponding BRD approaches which led to a significant number of papers in the literature until the late 1970s [1]. A typical contribution to this literature is the study of behavior of some quantities used in BRD tests, by Higgins and Tsokos [2]. They show that the use of two different priors for MTBF, which cannot be easily distinguished between at the prior stage, can lead to substantial differences in the posterior risks in BRD. From this, we can conclude that choice of the prior distribution was known to be crucial and problematic in BRD, yet it has received relatively little attention in the BRD literature.

Since the early 1980s, BRD seemed to disappear as a main topic from the reliability literature, with further development mostly in industry, so less frequently reported in the academic literature, and often embedded in wider programmes for achieving

quality and reliability. Examples of such progress on methods for reliability demonstration, including Bayesian approaches, in the automotive industry are presented by Lu and Rudy [3, 4]. Recently, Yadav *et al.* [5] raised interesting issues on reliability demonstration, emphasizing the need for a comprehensive approach which integrates reliability demonstration into the product development process. They emphasize that three dimensions of product design must be considered: physical structure, functional requirements, and time in service. They propose some statistical methodology for specific distributions and test plans, but although they mention the importance of including prior information, they do not formalize this nor do they use a Bayesian approach. This work, however, provides interesting arguments for renewed interest in BRD.

In recent years, the current authors have presented, in part jointly with Rahrhrouh, a different perspective on BRD, focussing solely on attribute testing [6–10]. This work has mainly been motivated by the observation that methods presented in the literature seemed not to take explicitly into account characteristics of the process in which the system is to be used after BRD testing, nor practical constraints on such testing. For example, they distinguished between the cases of catastrophic and noncatastrophic system failure in the process after testing, and they also studied optimal decisions for both BRD and choice of **redundancy** level in a system, from overall cost perspective. They also considered the role and choice of the prior distribution in BRD in detail, which is crucial yet far from trivial and had not yet received much attention. We briefly summarize main results in the sections “Zero-Failure Reliability Demonstration” and “The Prior Distribution”, illustrated by some examples in the section titled “Examples”, and discuss some further aspects in the section titled “Summary and Related Topics”.

Zero-Failure Reliability Demonstration

Martz and Waller [11] considered the before mentioned risk-based BRD from the perspective of only tests that reveal zero failures. This has two advantages. First, in practical demonstration of, particularly, high reliability, occurrence of one or more failures goes against the very nature of reliability demonstration, and is likely to lead to improvement

actions of the system, where possible, followed by renewed reliability demonstration. This cycle brings with it very important challenges, also called “test-fix-test”, which are beyond the scope of this paper. The second advantage of restricting attention to inference only valid when testing reveals zero failures, is the relative mathematical simplicity of the resulting Bayesian posterior and corresponding predictive distributions, enabling these to be embedded in wider decision-theoretic frameworks involving aspects of the process in which the system is required after testing, and inclusion of costs and time considerations and constraints. This and the following two sections provide some details of such a predictive approach to zero-failure BRD, with attention restricted to attribute testing [6–10].

We consider systems which have to deal satisfactorily with tasks of k different types, where we assume complete independence between tasks of different type (both in the success probability of the system to deal with such different tasks, and in the statistical sense). In a standard Bayesian setting [1, 12, 13], we use a Binomial model for the number of failures in n_i tests of tasks of type i , for $i = 1, \dots, k$, with parameter θ_i representing the unknown probability of a failure when the system has to deal with a task of type i . We assume a Beta (α_i, β_i) prior distribution for θ_i , and we further assume that zero failures will be observed in the n_i tests, denoted as data $(n_i, 0)$, so these inferences are only valid for zero-failure BRD. The corresponding posterior predictive probability of zero failures in m_i tasks of type i , in the process after such testing, is

$$P(0|m_i, (n_i, 0)) = \prod_{j=1}^{m_i} \frac{j + \beta_i + n_i - 1}{j + \alpha_i + \beta_i + n_i - 1} \quad (1)$$

For $n_i > 0$, (1) holds for $\alpha_i > 0$ and $\beta_i \geq 0$. Because no failures are observed we cannot use $\alpha_i = 0$, as the corresponding posterior distribution would be improper [12]. The hyperparameters α_i and β_i can be interpreted in terms of results of an imaginary earlier test of $\alpha_i + \beta_i$ tasks of type i , in which the system failed to deal with α_i such tasks, but performed β_i such tasks successfully. For BRD, this implies that inferences are quite insensitive to choice of β_i , where an increase in β_i means that the minimal required n_i is reduced by the same number. However, such inferences are highly sensitive to the choice of α_i , as effectively the reliability demonstration requires n_i

tests without failures to counter the prior information of α_i “imaginary test failures”. We discuss the choice of the prior distribution in more detail in the section titled “The Prior Distribution”, where we will advocate the use of Beta prior distributions with $\alpha_i = 1$ and $\beta_i = 0$. It should be noted that this chosen value for β_i leads to an improper prior distribution, so formally not really a probability distribution as it does not integrate to one over the parameter space. No statistical inferences can be based on improper distributions, but in this setting we assume explicitly that, for posterior inference for demonstrating reliability, the data contain a positive number of observed successes, which ensures that the corresponding posterior distribution is proper.

We briefly state some results from [8], on required test numbers n_i , such that zero failures in testing ensures a probability p of no failures in the process, either for deterministic number of tasks or for a stochastic process considered over a fixed period of time. This setting is, for example, suitable for catastrophic failures, that is, a failure leads to break-down of the whole system, in the sense that the clear target is to demonstrate reliability *via* an inferred (very) high probability of zero failures in the process after testing, when the system is actually in service. In such cases (e.g. alarm systems for chemical plants), it is often difficult to bring cost considerations into the argument, either due to inherent lack of knowledge of consequences of rare events or due to ethical issues, so requirements directly on the predictive probability of zero failures are attractive. Of course, such cost considerations are likely to influence choice of an appropriate value of p .

For the deterministic case, where the system must perform a known number m_i of tasks of type i in the process, the n_i must be such that

$$P(0|m_i, (n_i, 0), i = 1, \dots, k) = \prod_{i=1}^k \prod_{j=1}^{m_i} \frac{j + \beta_i + n_i - 1}{j + \alpha_i + \beta_i + n_i - 1} \geq p \quad (2)$$

If we aim at satisfying this requirement with a minimal total number of tests, there is no closed-form solution for n_i . For the special case with $\alpha_i = \alpha$, $s_i = \beta_i + n_i = s$ and $m_i = m$, for all i , an approximation for the minimum required value of s to meet this

reliability requirement, with p close to 1, is

$$\frac{p^{1/(k\alpha)}}{1 - p^{1/(k\alpha)}} \times m \quad (3)$$

For the case with $\alpha = 1$ and $\beta_i = 0$, for all $i = 1, \dots, k$, which we advocate for use in reliability demonstration (see the section titled “The Prior Distribution”), (equation 3) gives the exact value of the optimal (real-valued) n_i ’s [8] (the integer-valued solution is found by checking this probability value for the neighboring integer-valued k -vectors). The fact that, to minimize the total number of zero-failure tests required in this situation, one would indeed wish to use equal values of s_i , is proven in [8].

For p close to 1, the expression (3) is close to

$$\frac{p}{1 - p} \times k\alpha m \quad (4)$$

which can be proved *via* the same argument as used in [8] to show that equation (3) is approximately linear in k . The expression (4) makes clear that the required number of zero-failure tests is very sensitive to the choice of α . Clearly, the required value of n_i is less sensitive to small changes in β_i , as the sum of n_i and β_i must be a constant. The influence of the α_i and β_i on the required number of zero-failure tests is similar in more general situations with unequal α_i , s_i and m_i .

Of course, in many real-world processes the number of tasks m_i are not deterministic, which is for example typically the case in alarm systems. An important and interesting result is the following: let M_i be the random number of tasks of type i that the system has to perform in the process after testing. Then, for all possible probability distributions for M_i with the same expected value $E(M_i)$, the most BRD testing is actually required for the deterministic case with $m_i = E(M_i)$ (this is a consequence of Jensen’s inequality). Hence, as long as one can specify an expected value for the number of tasks the system will be required to perform (or of course an upper bound to stay on the safe side), then the amount of testing required by assuming this number to be deterministic leads to conservative test numbers. It also turned out from many examples studied, although formal proof was not achieved, that if M_i actually has a Poisson distribution, which is often suitable to model accidental events, then the optimal numbers of BRD tests of tasks of type i are

very close to the corresponding optimal test numbers in the deterministic case, which in practice means that over-testing would be prevented in such cases if you based your calculations upon the deterministic case instead of the Poisson case [8]. Example 1 in the section titled “Examples” illustrates this approach.

A different predictive BRD approach was presented in [9], which is suited for noncatastrophic system failure during the process after testing. This implies that the system will be able to continue operating in case such a failure occurs, and also that cost considerations become more important, so both costs of testing and of failure are taken into account. That approach aims at minimization of overall expected costs for testing and the process after testing, and takes constraints on testing (both budget and time) into account. Optimal BRD plans are derived by solving relatively straightforward constrained optimization problems, with several analytical results making clear the influence of constraints on testing. The reader is referred to [9] for more details, we wish to emphasize that it is again the predictive nature of this approach, with reliability criteria explicitly expressed in terms of the system’s performance in the process after testing, and using only observable random quantities (mostly the number of failures per type of task), which makes this an attractive solution to BRD.

In [10] a similar approach, yet again more suitable for catastrophic failures, is considered in which reliability of a system, to be demonstrated, is controlled both by tests and decisions on in-built system redundancy. This also considers minimization of total expected costs, taking into account the costs of additional redundancy which of course enables fewer zero-failure tests in order to demonstrate a required level of reliability, the latter typically included as a constraint for the optimization problem. We refer to [10] for further details, Example 2 in the section titled “Examples” shows the potential of this approach.

The important considerations of the role and choice of the prior distribution are similar for all the different predictive BRD approaches mentioned here, and are commented on in the next section.

The Prior Distribution

A main concern in Bayesian statistics is the choice of the prior distribution. In many applications, if sufficient data are observed then the inferences based

on the posterior distribution are pretty robust with regard to the choice of the prior distribution. In the zero-failure BRD setting, however, the posterior distribution remains highly sensitive to some changes in the prior distribution. Hence, it is not straightforward to use so-called “noninformative” priors [12] for such zero-failure testing [7, 8].

Design of experiments within the Bayesian framework is also strongly influenced by the prior distribution used [12]. It is usually advocated that the main role of the prior distribution is to take subjective information into account. From this perspective, the main aim of design of experiments, in Bayesian statistics, is for the person whose beliefs are modeled, to learn in some optimal manner from the data resulting from the experiment [14]. In case of testing for high reliability, one would often have quite strong prior beliefs about the quality of the system, in the sense that one would already expect the system to be highly reliable, such that one would be somehow surprised if there were still one or more failures observed during testing. If one takes such beliefs into account *via* a prior distribution, then this will lead to relatively few zero-failure tests being required in order to meet a reliability criterion. Using one’s prior beliefs as such, the intention of the tests would be to learn, in a way that is dependent on the subjective input. In the extreme case, if one is already so confident about the system’s reliability that one judges testing unnecessary, one can choose a corresponding prior distribution such that indeed no further testing is required. Of course, this may not convince others. A similar difference between personal learning and convincing others, affects general Bayesian design of experiments and the role of **randomization** [15].

We propose that the prior distribution used for Bayesian reliability *demonstration*, plays a different, nonsubjective, role, as reliability demonstration is not normally intended to convince only the person whose beliefs are modeled, of the reliability of a system, but to satisfy externally imposed rules or to convince others of the system’s reliability. From this perspective, the prior distribution can be regarded as reflecting neutral, or even pessimistic, prior information, which the test data must counter in order to *demonstrate* reliability.

From this perspective of reliability demonstration, we advocate the use of the Beta prior for θ_i , with hyperparameters $\alpha_i = 1$ and $\beta_i = 0$. The choice

of $\beta_i = 0$ is natural, given its interpretation and its effect on the required number of zero-failure tests [8]. An appropriate value of α_i is more open to discussion, and this choice has great impact on the number of zero-failure tests required. With the interpretation as “having seen α_i tests failing” before testing, our test criterion demands sufficiently many zero-failure tests, such that, on the basis of the combined information represented by this prior distribution and the test results, the reliability requirement is satisfied. The choice $\alpha_i = 1$ seems reasonable from this perspective, as it asks for sufficient zero-failure tests to outweigh one suggested earlier failure. We consider $\alpha_i = 1$ a fairly conservative choice, in the sense that many zero-failure tests are required to demonstrate high reliability. Hartigan [16] suggested the same prior distribution for similar conservative inferences. A further argument in favor of this choice of α_i and β_i results from analysis of this same problem from a different foundational perspective [6].

Examples

Example 1 This example illustrates the BRD approach from [8], with failures assumed to be catastrophic. It considers the optimal test numbers for a system that has to perform $k = 4$ types of tasks, using prior distributions with $\alpha_i = 1$ and $\beta_i = 0$ for all $i = 1, \dots, 4$. We aim at minimization of the total number of tests, assuming they reveal no failures, such that the resulting predictive probability (2) of zero failures in the process is at least p . For the deterministic case, let $\underline{m} = (1, 2, 4, 9)$. The corresponding optimal test numbers are given in Table 1.

This illustrates that very high reliability can only be *demonstrated* by very many zero-failure tests. For this setting, if tasks are assumed to arrive according to **Poisson processes**, with their expected numbers equal to the m_i used above, then the numbers of

zero-failure tests required are indeed nearly identical to those in Table 1. If we increase the m_i , then the required test numbers increase by about the same factor, for example optimal testing for $\underline{m} = (10, 20, 40, 90)$, and $p = 0.90$, is achieved by taking $\underline{n} = (699, 985, 1387, 2067)$.

Example 2 In this example we briefly illustrate the optimal zero-failure test numbers and numbers of components, for systems with redundancy [10]. We consider a **2-out-of-y system**, so for the system to function a minimum of 2 out of y components must function, and we assume components to function independently. We only consider the deterministic case, with the numbers of tasks of $k = 3$ independent types required in the process after testing equal to one, three and six, respectively. The optimal BRD zero-failure test numbers and optimal number of components y are presented in Table 2 for several cases. The cost per component installed is Q , C is the cost incurred if the system does not deal successfully with all 10 tasks in the process after testing, and $\underline{c}$ represents the costs of one test per type of task. Again we use Beta prior distributions with $\alpha_i = 1$ and $\beta_i = 0$ for all types of tasks, and the optimization criterion chosen is minimal expected overall costs, so for testing and the system’s functioning during the process considered after testing, with the constraint that the posterior predictive probability of zero failures in those 10 tasks after testing should be at least $p = 0.95$. The cases considered are:

- (1) $\underline{c} = (1, 1, 1)$, $C = 10\,000$
- (2) $\underline{c} = (20, 50, 50)$, $C = 10\,000$
- (3) $\underline{c} = (20, 50, 50)$, $C = 1\,000\,000$.

Obviously, higher built-in redundancy (larger y) requires fewer zero-failure tests. Cases (1) and (2) in Table 2 illustrate the fact that increasing testing cost c_i per test of type i , reduces the optimal number of zero-failure tests n_i , and may increase

Table 1 Optimal test numbers

p	n_1	n_2	n_3	n_4
0.90	70	98	139	207
0.95	144	204	287	429
0.99	737	1042	1474	2209
0.995	1479	2091	2956	4433

Table 2 Optimal numbers of zero-failure tests ($\underline{n}$) and components (y)

Case(s)	$\underline{n}, y$		
	$Q = 300$	$Q = 1000$	$Q = 3000$
(1)	(47, 68, 86), 3	(47, 68, 86), 3	(201, 347, 489), 3
(2)	(8, 9, 10), 5	(12, 12, 15), 4	(26, 28, 35), 3
(3)	(14, 14, 16), 8	(20, 21, 23), 6	(41, 43, 51), 4

the optimal y . For case (2) with $Q = 1000$, Table 2 shows that the optimal solution is to install $y = 4$ components with $\underline{n} = (12, 12, 15)$ zero-failure tests. If we increase the cost per component to $Q = 3000$ in the same setting, the optimal solution for case (2) is $y = 3$ components with $\underline{n} = (26, 28, 35)$ tests. If we consider a 2-out-of-2 system instead (not presented in Table 2), the optimal zero-failure test numbers, in this case, are (296, 322, 454). This illustrates that the option of building in redundancy can greatly reduce the test requirements and the corresponding expected costs. Cases (2) and (3) illustrate that increasing process failure cost C requires an increased number of components and/or an increased number of zero-failure tests to minimize the total costs and to demonstrate the required reliability level.

Summary and Related Topics

BRD is a topic of great interest, both for applications and from the perspective of foundations of statistics, the latter due to wide variety of possible reliability criteria and the nonstandard role prior distributions play when test data are required to *demonstrate* reliability. The predictive approach to BRD, recently presented by the current authors and discussed above, is promising in its flexibility with regard to reliability criteria used and the possible inclusion of constraints in the optimization problems considered to take practical considerations into account [17]. As this approach has so far only been developed for attribute testing, there are important challenges for a similar way for BRD involving (continuous) time random quantities. This is particularly challenging in zero-failure situations, where observations would only consist of observed periods without failures, so all observations would be right-censored (see [18] for a nonparametric predictive approach to a related problem in probabilistic safety assessment). There are many topics in statistics, quality control and reliability, which consider problems that are closely related to BRD, for example, **software reliability** verification and testing [19–21] and **acceptance sampling**, as well as topics such as fault removal and re-testing, and accelerated life testing [22], and linking these to BRD for large-scale systems and developing engineering projects is a major challenge, so BRD promises to offer exciting opportunities for research and applications over the next decades.

Software Reliability: Bayesian Analysis

Introduction

Software reliability is usually defined as the probability that a piece of software runs without failing under certain operational conditions for a given time. In the software testing phase, it is normally assumed that after a failure, the software is debugged, so that on average, **reliability growth** is observed. The most common software reliability growth models, starting from the approach of Jelinski and Moranda [1] (hereafter JM), try to explain the behavior of the interfailure times $T_1, T_2, \dots$ (type I models) or the point processes that they generate, $N_1(t_1), N_2(t_2), \dots$ (type II models). For a full review, see **Software Reliability Modeling and Analysis**.

Bayesian Inference: General Aspects

An advantage of the Bayesian approach is that it directly incorporates prior information *via* the elicitation (see **Prior Distribution Elicitation**) of expert opinions (see **Expert Opinion in Reliability**) or the use of failure data from previous projects (which are often available in software reliability problems) in the form of a prior distribution. Thus, given a model $\mathcal{M}$ for interfailure times T_i (similarly for other data types) and a prior distribution $f(\theta|\mathcal{M})$ for the parameters θ , then when data $\mathbf{t}_n = (t_1, \dots, t_n)$ are observed, the posterior distribution for θ is calculated from Bayes theorem as

$$f(\theta|\mathcal{M}, \mathbf{t}) \propto f(\theta|\mathcal{M})l(\theta|\mathcal{M}, \mathbf{t}_n) \quad (1)$$

where $l(\theta|\mathcal{M}, \mathbf{t}_n)$ is the likelihood function. Prediction is straightforward, for example the survivor function of the time to next failure T_{m+1} is

$$P(T_{m+1} > t|\mathcal{M}, \mathbf{t}_n) = \int P(T_{m+1} > t|\mathcal{M}, \mathbf{t}_n, \theta) \times f(\theta|\mathcal{M}, \mathbf{t}_n) d\theta \quad (2)$$

An important aspect of software reliability modeling is the software testing strategy. Various testing plans have been considered, for example, one stage testing for a single fixed time period, say T .

The choice of T is a decision problem and the Bayesian approach is to define a utility function $U(T|\mathcal{M}, \theta)$ which evaluates the gains and losses of each possible choice. The optimal Bayes decision is then to choose the option which maximizes the expected utility function

$$E[U(T|\mathcal{M}, \theta)] = \int U(T|\mathcal{M}, \theta)f(\theta|\mathcal{M}) d\theta \quad (3)$$

An initial application in software testing is [2] and a good general review is [3], Chapter 6.

Although many software reliability models have been proposed, no single model has been demonstrated to be globally superior and thus, model selection is important. The Bayesian approach uses the prequential likelihood and Bayes factors. As successive data, $t_1, t_2, \dots, t_n$ are observed, then the prequential likelihood of $\mathbf{t}_i = (t_1, \dots, t_i)$ for $i = 1, \dots, n$, given model $\mathcal{M}$ is

$$f(\mathbf{t}_i|\mathcal{M}) = \int f(\mathbf{t}_i|\mathcal{M}, \theta)f(\theta|\mathcal{M}) d\theta \quad (4)$$

see, for example [4]. The performance of two different models $\mathcal{M}_1$ and $\mathcal{M}_2$ can be compared by graphing the prequential likelihood ratio

$$B_2^1(\mathbf{t}_i) = \frac{f(\mathbf{t}_i|\mathcal{M}_1)}{f(\mathbf{t}_i|\mathcal{M}_2)} \quad (5)$$

Such graphics are used to illustrate the ranges of data for which one model outperforms another. The prequential likelihood ratio given the whole data set is called the *Bayes factor*, see [5], and is used to compare the relative credibility of the two models in a similar way as the classical likelihood ratio.

Bayesian Inference: Specific Models

Various type I “bug counting” models have been developed under the assumption that the program initially contains an unknown fixed number of faults, say N , and that as each failure occurs, then these faults are successively corrected. See, for example, [1, 6–8]. The first and simplest is the JM model, [1], which further assumes that the failure rate of T_i is directly proportional to $N - i + 1$ implying that given an additional parameter ϕ ,

$$T_i|N, \phi, \mathbf{t}_{i-1} \sim \exp((N - i + 1)\phi) \quad (6)$$

that is, an exponential distribution with rate $(N - i + 1)\phi$ where $\mathbf{t}_{i-1} = (t_1, \dots, t_{i-1})$. Given the observed data $\mathbf{t}_n$, the likelihood is

$$l(N, \phi | \mathbf{t}_n) = \frac{N!}{(N - n)!} \phi^n \times \exp \left\{ -\phi \left((N + 1) \sum_{i=1}^n t_i - \sum_{i=1}^n i t_i \right) \right\} \quad (7)$$

and in principle, inference could be carried out using maximum likelihood. However it has been demonstrated that **maximum likelihood estimation** often fails to provide sensible answers, see, for example, [9] and Bayesian methods should be preferred. In [9], the following **prior distributions** are suggested

$$N \sim Po(\lambda) \quad \phi \sim G(a, b) \quad (8)$$

that is, a Poisson distribution with mean λ for N and a gamma density for ϕ . Combining likelihood and priors in equations (7) and (8) it is easy to see that, *a posteriori*, conditional on ϕ , then $N - n$ has a Poisson distribution and given N , ϕ has a gamma distribution and therefore a Gibbs sampling scheme (see **Hierarchical Markov Chain Monte Carlo (MCMC) for Bayesian System Reliability**) as in [10] can be set up to sample the posterior parameter distributions.

A number of extensions to the basic approach have been developed. Hierarchical priors (see **Hierarchical Markov Chain Monte Carlo (MCMC) for Bayesian System Reliability**), for the parameters λ , a , b in equation (8) are introduced in [10, 11]. **Covariate** information in the form of software metrics is used in [12] and formal sensitivity analysis is undertaken in [13]. Finally, different software testing strategies were explored in [14, 15].

The alternative bug counting models cited all lead to similar likelihood functions and given a Poisson prior for N , can all be analyzed using Gibbs sampling techniques. In particular [16] provides a general Bayesian method for parametric bug counting models and a nonparametric approach is introduced in [17].

Other software reliability models are based on the idea of reliability growth, without taking fault numbers into account. Moranda [18] assumes that the failure rate of T_i is Dk^{i-1} so that

$$T_i | D, k, \mathbf{t}_{i-1} \sim \exp(Dk^{i-1}) \quad (9)$$

where $k < 1$, which implies that the failure rate always decreases (see [3, p. 166] for a Bayesian approach to this model). However, the assumption of a deterministically decreasing rate is very strong and a number of hierarchical models have been constructed by assuming exponential interfailure times $T_i | \lambda_i, \mathbf{t}_{i-1} \sim \exp(\lambda_i)$ and a further hierarchical prior for the failure rate λ_i to model the reliability growth. Littlewood and Verrall (hereafter LV), [19], proposed assuming

$$\lambda_i | \alpha, \psi(i) \sim \gamma(\alpha, \psi(i)) \quad (10)$$

where $\psi(i) = \beta_0 + \beta_1 i$ is an increasing function of i . Empirical Bayes parameter estimation (see **Empirical Bayes Estimation of Reliability**) for this model is introduced in [20] and a full Bayesian inference is studied for an extended model based on a polynomial $\psi(i)$ in [10]. In [21], a Markovian structure is used and the sequence of failure rates is assumed to be a martingale by Basu and Ebrahimi [22], where

$$\lambda_1 | \alpha, \beta \sim \gamma(\alpha, \beta),$$

$$\lambda_i | \lambda_{i-1}, \alpha \sim \gamma\left(\alpha, \frac{\alpha}{\lambda_{i-1}}\right) \text{ for } i > 1 \quad (11)$$

The majority of type II models, starting with Goel and Okumoto [23] and Musa and Okumoto [24], are based on nonhomogeneous Poisson processes so that the number of failures $N(t)$ in a time period of length t is assumed to have a Poisson distribution with some **intensity function** $\lambda(t)$. Bayesian inference for the Musa Okumoto model with the use of subjectively elicited expert priors is introduced in [25] and a general Bayesian approach for analyzing nonhomogeneous **Poisson process** (type I and type II) models is given in [16] and applied in [26]. Nonparametric estimation of the intensity function has been considered by [27, 28]. Finally, the use of covariate information such as software metrics in order to estimate the intensity function is examined in [29, 30].

An alternative approach to modeling interfailure times is to consider these as a **time series**. The following Bayesian autoregressive model (hereafter KF) is proposed in [31]

$$\log T_i = \alpha \theta_i + \epsilon_i \quad \theta_i = \alpha \theta_{i-1} + v_i \quad (12)$$

where ϵ_i and v_i are independent normal errors. Given a normal prior distribution for θ_0 , it is straightforward to calculate the predictive distributions of

future failures by Bayesian Kalman filtering, see, for example [32]. An extension to the case where α is unknown is given in [33]. An alternative, non-linear Kalman filter (NGKF) is introduced in [34] where

$$T_i | \theta_i \sim \gamma(v, \theta_i) \quad \phi_i = \frac{C\theta_i}{\theta_{i-1}} \sim \beta(\sigma, v) \quad (13)$$

that is a beta distribution, with prior distribution $\theta_0 \sim G(\sigma + v, u_0)$. When C is known, inference is straightforward and when C is unknown, various schemes for calculating the posterior distribution are available. A related idea of recent interest is the use of neural networks to model the time series. Bayesian regulation neural nets are examined in [35].

Example

Table 1, taken from [36] gives usage times between 34 successive failures, due to incorrect user documentation on a workstation.

The following models were fitted to this data:

- JM*: equation (6), with priors $N|\lambda \sim Po(\lambda)$, $\lambda \sim \gamma(0.1, 0.001)$, $\phi \sim \gamma(0.1, 0.1)$.
- LV*: equation (10) with $\alpha \sim \exp(1)$, $\beta_i \sim \exp(0.001)$ for $i = 1, 2$.
- Moranda*: equation (9) with $D \sim \gamma(0.1, 0.1)$ and $k \sim U(0, 1)$, a uniform distribution.
- KF*: equation (12) with $\epsilon_i \sim N(0, 4)$, $v_i \sim N(0, 0.004)$, and $\theta_0 \sim N(1, 1)$.
- NGKF*: equation (13) with $\theta_0 \sim \gamma(2, 1)$ and $C \sim U(0, 1)$.
- Basu*: equation (11) with $\beta \sim \gamma(0.1, 0.1)$ and $\alpha \sim U(0.25, 4)$.

Using the JM model as the base $\mathcal{M} = 1$, Figure 1 graphs the logs of the prequential likelihood ratios, (see equation (5)) in favor of the various alternatives.

The LV model performs best for most of the data but is finally overtaken by KF. As suggested in [36],

Figure 1 Log prequential likelihood ratios of alternative models versus JM

Figure 2 Predictive survivor functions for the LV, KF, NGKF, and Basu models

there appears to be a change point in the data at around the 30th failure.

Figure 2 illustrates the predicted survivor functions, see equation (2) for the time to next (35th) failure for the four best performing models.

The time series and Basu Ebrahimi models, which fit the last few interfailure times well are similar whereas the Littlewood-Verrall model provides much less confident predictions.

Table 1 Interfailure times data

1339	163	2582	583	202	337	112	373	383	44	72	77
179	87	23	40	427	165	21	75	131	251	775	175
105	561	1397	1601	552	4876	30767	710	20867	34789	—	—

Other Approaches to Software Reliability

Although this article has studied software reliability models based on interfailure times, there are other approaches. One method tries to relate software metrics, for example, lines of code to software quality. Recent work in this area has used Bayesian belief nets or graphical models, see [37]. Graphical models have also been applied to partition testing, that is, the choice of test cases in order to maximize the probability of fault detection (see e.g. [38]).

MICHAEL P. WIPER

Statistical Process Control, Bayesian

Introduction

Historically, **quality management** was driven largely by specification limits. In **acceptance sampling** for quality assurance, for example, items would be classified as defective or nondefective, based either on a qualitative assessment or their conformity to the specification limits. The seminal work of Shewhart [1] and more recent thinking by Taguchi [2] changed this focus, relegating specification limits to the background and concentrating on the “common cause” variability of the process. As long as the process readings lay within the range of common cause variability, the process would be left untouched, and when it appeared that the process was outside the range of common cause variability, it would be inferred that a “special cause” had intervened, and a search for and correction of the special cause would follow. From a statistical viewpoint, Shewhart’s charts can be thought of as repeated hypothesis tests, implemented graphically. For example, if the common-cause variability in a process measurement is that the measurement stream behaves like independent $N(\mu_0, \sigma_0^2)$ variables, then the Shewhart Xbar chart can be thought of as a repeated test of the null hypothesis that the current mean μ equals μ_0 , and the R or S chart as a repeated test of the null hypothesis that the current standard deviation σ equals σ_0 . Good book-length discussions of the area can be found in, for example, [3] and [4].

Bayesian Formulations of Charts

Quantifying this common cause variability in a frequentist sense, however, requires that large phase I samples be gathered. This substantial overhead, always undesirable, is impossible in short-run and start-up settings. It is also a failing of the frequentist approach typified by Shewhart charting that it is not able to make use of the prior information that is frequently available even in start-up and short-run problems. For example, when we start up a lathe to turn 6 mm bolts, previous experience using that lathe to turn 5 mm bolts is clearly relevant to this new

but similar problem, but hard to accommodate in a frequentist framework.

An early development of a Bayesian approach was that of Shirayayev [5] and subsequently Roberts [6]. These approaches may be thought of as Bayesian change point formulations [7, 8]. While the process is “in control” and only common causes operate, the process measurements X_n are modeled as following a common independent distribution $f_0(\cdot)$. At some unknown time point τ , a special cause may intervene, changing the distribution to $f_1(\cdot)$. This changed distribution may be of the same form as f_0 : for example both might be normals with the same variance but different mean, corresponding to a step change in mean, but the theory allows for general shifts. The shift in distribution remains until detected and diagnosed.

The likelihood of a sequence of data is

$$f(x_1, \dots, x_n | \tau) = \prod_{i=1}^{\min(n, \tau-1)} f_0(x_i) \prod_{j=\tau}^n f_1(x_j) \quad (1)$$

(the second product being absent if $n < \tau$).

In Shirayayev’s work, f_0 and f_1 were considered fully known, and τ modeled (*a priori*) by a geometric distribution with probability p of a shift at any observation. Shirayayev showed that $P_n = P(\tau \leq n | x_1, x_2, \dots, x_n)$, the posterior probability that the shift occurred before the n th observation is:

$$\begin{aligned} P_n &= \frac{\frac{p}{(1-p)^{n+1}} \sum_{k=1}^n (1-p)^k \prod_{j=k}^n \frac{f_1(x_j)}{f_0(x_j)}}{\frac{p}{(1-p)^{n+1}} \sum_{k=1}^n (1-p)^k \prod_{j=k}^n \frac{f_1(x_j)}{f_0(x_j)} + 1} \\ &= \frac{R_n^S}{R_n^S + 1} \end{aligned} \quad (2)$$

This posterior probability can be used to decide whether to stop the process on the grounds that the process has undergone a step change. Shirayayev in [5] provided the optimal stopping rule in the case where the distribution laws $f_0(\cdot)$ and $f_1(\cdot)$ are known: if a false alarm (stopping before there has been a change) costs 1 unit, and signaling a change at time $N > \tau$ costs $c(N - \tau)$ units, then the optimal (Bayes) solution is to stop at the smallest N for which the posterior probability $P_n \geq p^*$ for some predetermined value $0 < p^* < 1$ (close to

2 Statistical Process Control, Bayesian

1). According to Bather [9] if we wish to bound the expected false alarms by K , then the optimal $p^* = (K + 1)^{-1}$.

Letting p approach zero (following the realistic assumption that these step changes are infrequent) leads to the Shiriyayev–Roberts [6] procedure:

$$R_n^{SR} = \sum_{k=1}^n \prod_{i=k}^n \frac{f_1(x_i)}{f_0(x_i)} \quad (3)$$

and using the same loss function as above we obtain the following stopping rule:

$$N^{SR}(\gamma) = \inf \{n \geq 1 : R_n^{SR} \geq \gamma\} \quad (4)$$

The SR statistics (3) can also be given recursively: $R_0^{SR} = 0$ and for $n = 1, 2, \dots$

$$R_n^{SR} = (1 + R_{n-1}^{SR}) \frac{f_1(x_n)}{f_0(x_n)} \quad (5)$$

This equation is reminiscent of Page's [10] cumulative sum (**cusum**) statistic recursive formula:

$$W_n = \max_{1 \leq k \leq n} \prod_{i=k}^n \frac{f_1(x_i)}{f_0(x_i)} = \max\{W_{n-1}, 1\} \frac{f_1(x_n)}{f_0(x_n)} \quad (6)$$

a powerful frequentist tool in detecting (even small) persistent shifts in the distribution law, and whose performance is quite like that of the SR method under minimax criteria.

The Chernoff and Zacks [11] model is another change point with several notable differences from the Shiriyayev–Roberts approach. It avoids the fully specified SR setup, allowing unknown distributional parameters. So it is able to provide, not only inference on when the change occurred, but also the posterior distribution of the parameter of interest. More specifically the distributional model is a **normal distribution** with constant variance assumed without loss of generality (since it is assumed known) to equal 1. The mean at observation n is θ_n . If there has been no change, then $\theta_n = \theta_{n-1}$, but following a change $\theta_n = \theta_{n-1} + Z_n$, where Z_n is a normally distributed increment in the mean.

This model allows for multiple changes in the mean, and leads to computationally challenging expressions for its posterior distributions. A substantial simplification is Zacks and Kenett [12] AMOC

(at most one change) model. Reminiscent of the Shiriyayev formulation, this holds that

$$\theta_i = \begin{cases} \theta_0 & i = 1, \dots, \tau - 1 \\ \theta_1 = \theta_0 + Z, & i = \tau, \dots, n \end{cases} \quad (7)$$

but differs in that, rather than being constants known *a priori*, $\theta_0 \sim N(\mu_0, \sigma^2)$, $Z \sim N(\delta, \rho^2)$ are random variables.

This setting shows some philosophical differences from the Shewhart thinking, where the in-control mean μ_0 represents the mean when things are going right in the system. In all the change point approaches, μ_0 is simply the mean when the system is first observed. That the system is going right at that time is not an automatic given, but the result of care and attention on the part of the process owner.

A final generalization to be mentioned in this thread is that of Tsiamyrtzis and Hawkins [13], who considered a random walk model with occasional shocks for the mean of normally distributed data, that is, we observe:

$$X_n | \theta_n \sim N(\theta_n, \rho^2) \quad (8)$$

and the means obey the following:

$$\begin{aligned} &\theta_n | \theta_{n-1} \\ &\sim \begin{cases} N(\theta_{n-1}, \sigma^2) & \text{with probability } p \\ N(\theta_{n-1} + \delta, \sigma^2) & \text{with probability } 1 - p \end{cases} \end{aligned} \quad (9)$$

with $\theta_0 \sim N(\zeta, \sigma_0^2)$. Then the posterior distribution of θ_n given the data: $\mathbf{X}_n = (x_1, x_2, \dots, x_n)$ will be given as a mixture of 2^n normal distributions of the form:

$$p(\theta_n | \mathbf{X}_n) = \sum_{i=0}^{2^n-1} \alpha_i^{(n)} N(\theta_i^{(n)}, \hat{\sigma}_n^2) \quad (10)$$

where the weights, means and variance are provided recursively.

Here the equivalence between being out of control to the parameter having changed falls away; rather the process is out of control when the current mean has drifted too far from its initial acceptable level. This feature of the approach meshes with six-sigma thinking that the process can be left alone as long as the mean is no more than 1.5 standard deviations from its nominal setting.

The Kalman Filter

This last development brings us to the Kalman filter (KF) [14]. **SPC** ideas tend to be motivated by the idea of sudden discrete changes from some fixed in-control model to another fixed out-of-control model. The KF has a steadily changing parameter with no sudden jumps:

$$\theta_n = G_n \theta_{n-1} + w_n \quad (11)$$

where G_n is assumed known, and w_n induces the random drift in θ . Generalizing the standard SPC model

$$X_n \sim N(\theta_0, \sigma_0^2) \quad (12)$$

in the KF we have

$$X_n \sim N(F_n \theta_n, \sigma_0^2) \quad (13)$$

The parameter θ_n may be vector-valued. The success and wide adoption of the KF are helped by its simple recursive updating formulas.

Count Data

Shewhart methods for nonconformities are embodied in the C and U charts. The milestone in development of Bayesian alternatives is perhaps Hoadley's [15] quality measurement plan (QMP).

At time period n write X_n for the number of defects (nonconformities) in the sample, e_n for the expectation function discussed below, and θ_n for the true population index. As usual with count data, we use a Poisson model

$$X_n | \theta_n \sim \text{Poisson}(e_n \theta_n) \quad (14)$$

so the expected value of X_n involves an unknown parameter θ_n multiplying a known expectation coefficient e_n . These are calibrated so that while the process is operating correctly, θ_n should equal 1, that is, e_n should be the expected value of X_n .

The process parameter θ_n is assumed to follow a gamma prior distribution:

$$\begin{aligned} \theta_n | (\alpha, \beta) &\stackrel{iid}{\sim} \gamma(\alpha, \beta) \quad \text{with} \\ \pi(\theta_n | \alpha, \beta) &= \frac{\beta^\alpha}{\Gamma(\alpha)} \theta_n^{\alpha-1} e^{-\beta \theta_n} \end{aligned} \quad (15)$$

leading to the posterior distribution

$$\theta_n | (x_n, \alpha, \beta) \sim \gamma(\alpha + x_n, \beta + e_n) \quad (16)$$

The QMP graph is a time-ordered sequence of box and whisker plots with the box marking the 5 and 95th percentile and the whiskers the 1st and 99th percentile of the posterior distribution. Under squared error loss the Bayes (point) estimate of the parameter of interest (θ_n) is the mean of the posterior distribution, that is,

$$\hat{\theta}_n = \frac{\alpha + x_n}{\beta + e_n} \quad (17)$$

which is used as the center line in the box.

The process is deemed to be out of control if the lower whisker ends above the value 1, while an alert state, analogous to Shewhart warning limits, occurs if the box lies above the value 1.

Prior Parameters

In the parametric Bayesian approach, once the parametric form of the prior distribution has been decided (by either similar historic data or expert's opinion) we are left with the question of what the values of the prior distribution parameters (hyperparameters) will be. Two standard approaches for getting this needed information are **empirical Bayes** (EB) and purely Bayes (PB) approaches.

The EB approach is based on the fact that the marginal distribution of the data will depend on these hyperparameters and thus estimates can be obtained using the data. Therefore the EB approach requires the data in advance and so it can not be employed in the very beginning stage of the process, where the data will become available sequentially. It naturally follows that the more the data the better the estimates will be.

On the other hand in the PB approach the data are not allowed to be used twice in the modeling (first in estimating the hyperparameters and secondly in the Bayes theorem to provide the posterior distribution). Thus for the hyperparameters in cases where we are not able to provide some point estimates (coming from expert's opinion and/or other historic data—not the one we observe) a (second level) prior distribution can be used (hyper-prior). Under this scenario we can also incorporate hierarchical settings, where the prior distribution itself might depend on other

random quantities which we can simply model with a hyper-prior. So hierarchical schemes fit naturally in this context, something that is largely beyond the capabilities of straightforward frequentist models.

Finally, these approaches are not mutually exclusive; a PB approach can be used for an initial prior distribution, and then modified using EB prior to use in the actual charting.

An Evaluation of Bayesian SPC

The tension throughout statistical practice between frequentist and Bayesian approaches is present in SPC as well. It is fair to say though that Bayesian methods have gained less traction in SPC than in other areas of statistics.

Some of the reasons for this are the same inertia and resistance to change that cause some users who would benefit from a switch to cusums or exponentially weighted moving average (EWMAs) to continue their reliance on $\bar{X}$ and R charts. Some of the objections are resistance to Bayesian ideas as a matter of principle, and sometimes to the misconception that all informative priors come from some personalized and irreproducible introspection.

Along with these bad reasons is one with an element of validity: the much greater computational load involved in many of the Bayesian methods. For example, the Chernoff–Zacks Bayesian approach to the Shewhart question of a shift out of control leads, at the n th observation, to a mixture distribution with 2^n components that, unless tamed with some approximations, becomes unmanageable once the process is much beyond a dozen readings.

Beyond the straightforward natural conjugate priors, many Bayesian posteriors do not have closed forms, but must be addressed by estimation or approximation. Recent work in Markov Chain Monte Carlo (MCMC) has vastly simplified this process, but it remains beyond the scope of a nontechnical user who may be well able to use frequentist Shewhart, cusum or EWMA charts.

Turning to the other side of the comparison, what benefits accrue from using Bayesian SPC? The primary one is the ability to incorporate prior information in a natural seamless way, and to get the monitoring of the process up and running immediately, without the cumbersome preliminary phase I data-gathering exercise required by traditional frequentist

approaches. Always valuable, an early start is indispensable in short-run processes which do not run long enough to ever provide the several hundred phase I observations that are now recognized as necessary to calibrate known-parameter frequentist charts.

A further less tangible benefit is that the approach provides a full posterior distribution for any parameter of interest. This leads to the possibility of using a much richer array of inferential tools [16] than such binary observations as whether the current $\bar{X}$ lies inside or outside a Shewhart control limit. This posterior distribution allows us to check at each stage of the process, not only for quality **degradation** (as in frequentist's SPC), but for potential quality improvement as well. Furthermore within the Bayesian framework it is straightforward to obtain the predictive distribution [17] which can be used in forecasting and/or model assessment.

Last but not least is the fact that within the Bayesian framework, problems with multiple parameters are handled no differently than those with a single parameter, and there is no essential distinction between parameters of interest and nuisance parameters, except that in the final stages the latter are integrated out.

We argue that Bayesian approach should be used at all times where there is some prior information on process parameters. The benefit of the Bayesian formulation is that gives a unified framework which can take into account the prior information and seamlessly incorporates additional process observations.

As the prior information is most valuable when there is not much direct information, it is reasonable therefore to expect that the Bayesian approach will make substantial inroads in settings where the direct process measurements are less available: in short-run job-shop settings, where relevant informative prior information is common and large frequentist phase I exercises are impossible. In settings where large phase I data gathering is possible, the Bayesian approach may be attractive even to frequentists in providing a bridge allowing process monitoring to begin much sooner than is possible with the classical methods.

Bayesian Reliability Analysis

Introduction

Bayesian methods embody the eighteenth century philosophical approach of Rev. Thomas Bayes (1702–1761), a Presbyterian minister and mathematician. The hallmark of Bayesian methods is the use of Bayes’ theorem to incorporate pertinent supplementary knowledge and information not contained in the sample data. Loosely, we define *Bayesian inference* as those statistical methods in which, prior to the consideration and use of sample data, the uncertainty regarding the unknown values of the parameters in an assumed sampling distribution for the data is expressed by means of a prior distribution. Gelman *et al.* [1] provide a nice introduction to Bayesian methods.

In the Bayesian approach, the model consists of two parts: the likelihood function and the prior distribution. The *likelihood function* is constructed from the *sampling distribution* of the data, which describes the probability of observing the data before the experiment is performed. Once we perform the experiment and observe the data, we can consider the sampling distribution as a function of the unknown parameters. This function (or any function proportional to it) is called the *likelihood function*.

We treat the unknown parameters in the likelihood function as random, and a **probability density function** describes our uncertainty about them. This probability density function is the joint *prior distribution* for the parameters. In a Bayesian reliability analysis, the likelihood function and the prior distribution are combined using Bayes’ theorem, forming the basis for parameter **estimation**, statistical inference, and test design.

One major philosophical difference from the classical frequency-based methods is the notion of probability that is considered. Classical methods use the well-known *relative frequency* notion of probability. In contrast, subjective probability forms the cornerstone of Bayesian methods, which consider probability to be a subjective assessment of the state of knowledge (also called *degree of belief*) about reliability parameters of interest.

A reliability analyst often has access to relevant supplementary information about the value of the unknown reliability parameters from such sources as physical/chemical theory, computational analysis, process development testing, past experience with similar devices, generic reliability data, and **expert opinion**. The use of such added resources is an extremely useful and powerful component in the Bayesian approach.

The prior distribution describes the analyst’s state of knowledge about the parameter’s value prior to obtaining the sample data x . We note that in reliability analysis, the data x often contain *censored* observations (see [2]). After obtaining the sample data, the uncertainty associated with the parameter is fully expressed by the *posterior distribution* that is calculated *via* Bayes’ theorem. For the case of continuous random variables, *Bayes’ theorem* combines the prior distribution and the likelihood; namely,

$$\pi(\theta|x) = \frac{f(x|\theta)\pi(\theta)}{\int f(x|\theta)\pi(\theta) d\theta} \quad (1)$$

where $\pi(\theta|x)$ denotes the posterior distribution of the parameter θ , $\pi(\theta)$ represents the prior distribution of θ , and $f(x|\theta)$ denotes the sampling distribution of x (or *likelihood function* when considered as a function of θ given x). Hamada *et al.* [3] presents a thorough treatment of Bayesian reliability analysis.

Appeal of Bayesian Reliability Methods

The use of deductive reasoning embodied in equation (1) is straightforward. Consequently, Bayesian reliability methods are easy to follow and the corresponding estimates are easy to interpret. For example, a Bayesian *credible interval* (or Bayesian **confidence interval**) may be directly interpreted as a probability statement about θ in contrast to a corresponding (frequency-based) confidence interval that has no such direct probabilistic interpretation.

There are several other appealing aspects of Bayesian reliability methods. In most cases, for large sample sizes of test data, the difference between Bayesian and classical inferences will be insignificant. However, when test data are scarce, the differences are often significant, and Bayesian credible intervals based on informative priors are often narrower than classical confidence intervals. If the prior

distribution is essentially noninformative, then the Bayesian and classical estimates are often virtually the same.

An important situation arises for a binomial or Poisson sampling model when no failures have occurred. In this case, the classical *maximum-likelihood* estimate of the binomial failure probability or Poisson failure rate is zero, which is clearly too optimistic. Although there exist a variety of classical methods for rectifying this shortcoming, Bayesian point estimates are naturally nonzero.

Because Bayesian interval estimates of parameters are true probability statements about unknown parameters, they may be easily propagated through complex system models, such as **Bayesian networks, fault trees**, event trees, and other logic models. Except in the simplest cases, it is difficult to propagate classical confidence intervals through such models. Features and nuances of real-world reliability problems, such as complex censoring, random hierarchical effects, and so on, can easily be accommodated and modeled by Bayesian methods (see the section titled “Example”). Such features are often difficult to consider when using frequentist methods.

Bayesian inference provides a natural and convenient method to update our state of knowledge about a parameter as future additional test data are obtained. Bayes’ theorem accomplishes this update. Also, the Bayesian *predictive distribution*

$$f(y|x) = \int f(y|\theta)\pi(\theta|x) d\theta \quad (2)$$

is the posterior distribution of a “future” sample observation y given the current sample data x . Such predictive distributions are extremely useful in practice.

Finally, using Bayesian methods, it is easy to numerically calculate the posterior distribution for any quantities of interest involving θ , such as mean time to failure (MTTF), **quantiles** of the lifetime distribution, reliability, and so on. This is perhaps the most useful and appealing feature of Bayesian reliability methods (see the section titled “Example”).

Bayesian computations, such as the integration in the denominator of Bayes’ theorem, can be complex; a decade or so ago they were often essentially impossible to perform. However, such computations are now straightforward using modern computer software based on **Markov chain Monte Carlo** (MCMC) algorithms. MCMC makes the Bayesian

approach to reliability feasible and easy to do, particularly for hierarchical problems (see the section titled “Example”).

There are several MCMC computer software packages available. Perhaps the most widely used package is WinBUGS [4], a Windows-based implementation of BUGS (Bayesian inference Using Gibbs Sampling). The package contains flexible software for the Bayesian analysis of complex statistical models using MCMC methods. It is available for free download from the Internet at <http://www.mrc-bsu.cam.ac.uk/bugs/>.

Example

We now illustrate an MCMC-based Bayesian reliability analysis. Gerstle and Kunz [5] provide the failure times (in hours) for pressure vessels that have been wrapped in Kevlar 49 fibers and subsequently tested at four different fiber stresses: 23.4, 25.5, 27.6, and 29.7 megapascals (MPa). The data are shown in Table 1. The fibers were taken from eight different spools of material (labeled 1–8). We are interested here in (a) determining the effect of stress on lifetime and (b) estimating the reliable life for 99% of the population (i.e. estimating the 0.01 quantile of the lifetime distribution).

In the Bayesian analysis below, we consider the eight spools to be a random sample from a population of such spools in which each spool potentially contributes a unique random “spool effect” to the lifetime. This random effect is called a *hierarchical* effect because we consider a second-order prior distribution (or *hyperprior*) on the unknown parameters of the distribution of this effect. Note also that 11 of the 23.4 MPa tests were terminated at 41 000 h (i.e. *time censored*) without having resulted in a failure. Under the assumption of a Weibull failure time distribution with a constant shape parameter for all four stress levels, these data were analyzed using classical (frequentist-based) methods by Crowder *et al.* [6]. Both the original and the Crowder analyses concluded that there is a significant spool effect.

We likewise assume a Weibull failure time model with a constant (but unknown) shape parameter. Let t_{ij} , $i = 1, \dots, 8$, $j = 1, \dots, n_i$, denote the failure time for the j th observation taken from the i th spool, and let t denote all the data (including the 11 time-truncated observations). Thus, conditional on

Table 1 Failure times of Kevlar 49 wrapped pressure vessels at four stress levels

Stress (MPa)	Spool	Failure times (h)
29.7	1	444.4, 755.2, 952.2, 1108.2

^(a)Time censored

Weibull scale parameter λ_{ij} and shape parameter β , we assume that

$$t_{ij} \sim \text{Weibull}(\lambda_{ij}, \beta) = \lambda_{ij} \beta t_{ij}^{\beta-1} \exp(-\lambda_{ij} t_{ij}^{\beta}),$$

$$t_{ij}, \lambda_{ij}, \beta > 0 \quad (3)$$

Let us consider a so-called *power-law* model for λ_{ij} , which, upon taking logarithms, becomes

$$\log(\lambda_{ij}) = \gamma_0 + \gamma_1 \log(s_{ij}) + \omega_i \quad (4)$$

where ω_i is the random contribution of the i th spool, s_{ij} denotes the value of stress s under which t_{ij} was obtained, and γ_0 and γ_1 are two regression parameters used to model the assumed linear dependency of $\log(\lambda_{ij})$ on $\log(s_{ij})$. Denoting the vector of spool effects as ω , we further assume that, conditional on λ_{ij} and β , the t_{ij} are statistically independent.

Consider the following **prior distributions**. Conditional on σ , we assume that $\omega_i \sim \text{Normal}(0, \sigma)$ and place a diffuse Gamma(0.001, 0.001) prior distribution on the associated *precision* parameter $\tau = 1/\sigma^2$ (in conformance with WinBUGS convention to consider Gaussian precision rather than variance). *A priori* we believe that β is close to 1.0; thus, we consider $\beta \sim \text{Gamma}(3, 3)$. We consider diffuse priors on the remaining two parameters γ_0 and γ_1 ; namely, $\gamma_0 \sim \text{Normal}(0, 10^3)$ and $\gamma_1 \sim \text{Normal}(0, 10^3)$.

We use MCMC to obtain a set of N joint posterior draws on $\beta, \gamma_0, \gamma_1, \omega$, and σ given t , which we denote as $\{(\beta_l, \gamma_{0l}, \gamma_{1l}, \omega_l, \sigma_l), l = 1, \dots, N\}$. The WinBUGS computer software discussed earlier was used to obtain $N = 10\,000$ of these posterior draws. The marginal posterior distributions calculated from these 10 000 draws for each of the 12 parameters are summarized in Table 2.

In Table 2 we see that the majority of the support for the marginal posterior distribution of β is slightly above 1.0. Likewise, by examining the marginal posteriors of γ_0 and γ_1 , we observe a rather strong effect of stress on the Weibull scale parameter. Indeed, we also see a strong spool effect by noting that the majority of the support for σ exceeds 1.0.

Table 2 Summaries of the marginal posterior distributions on $\beta, \gamma_0, \gamma_1, \omega$, and σ given t in the Kevlar example

Parameter	Mean	Standard deviation	5th percentile	Median	95th percentile
β	1.17	0.08	1.04	1.18	1.28
γ_0	-97.12	5.82	-104.90	-98.00	-83.74
γ_1	26.91	1.65	23.20	27.15	29.14
ω_1	-1.56	0.74	-2.71	-1.57	-0.38
ω_2	0.87	0.74	-0.20	0.83	2.02
ω_3	1.68	0.77	0.57	1.64	2.94
ω_4	-2.12	0.75	-3.30	-2.13	-0.94
ω_5	0.11	0.77	-1.06	0.09	1.32
ω_6	0.35	0.75	-0.77	0.32	1.56
ω_7	2.25	0.79	1.10	2.20	3.52
ω_8	-0.91	0.75	-2.05	-0.93	0.27
σ	1.76	0.61	1.06	1.63	2.89

4 Bayesian Reliability Analysis

The effect that spools 1, 3, 4, and 7 have on the scale parameter is especially pronounced.

Before continuing, one might question whether or not the preceding modeling assumptions are supported by the data. In other words, what is the *goodness of fit* of the model to the data? Using five bins, the value of the Bayesian χ^2 goodness-of-fit test statistic developed by Johnson [7] is computed to be 4.1. Comparing this to a χ^2 distribution with 4 **degrees of freedom**, we find that the p value for testing whether the above Weibull regression model “fits” the data is 0.39. Thus, there is ample evidence to suggest that the assumed model agrees with the data.

The effect of stress on lifetime can be seen by computing the posterior distribution of the Weibull MTTF as a function of s for a randomly selected spool of Kevlar material. Now the MTTF of the Weibull distribution in equation (3) is $\lambda^{-1/\beta} \Gamma(1 + 1/\beta)$ which, upon taking logarithms, substituting equation (4), and simplifying, becomes $-(\gamma_0/\beta) - (\gamma_1/\beta) \log(s) - (1/\beta)\omega + \log[\Gamma(1 + 1/\beta)]$. For the 10000 joint posterior MCMC draws on β , γ_0 , γ_1 , and σ given t , and a given value of s , the corresponding posterior draws on $\text{Log}(\text{MTTF})$ are given by

$$\left\{ \frac{-\gamma_{0\ell}}{\beta_\ell} - \left(\frac{\gamma_{1\ell}}{\beta_\ell} \right) \log s - \left(\frac{1}{\beta_\ell} \right) \log \omega_\ell + \log \left[\Gamma \left(1 + \frac{1}{\beta_\ell} \right) \right], \ell = 1, \dots, 10000 \right\} \quad (5)$$

where $\{\omega_\ell \sim \text{Normal}(0, \sigma_\ell), \ell = 1, \dots, 10000\}$ denotes a set of additional Gaussian posterior draws on ω . These additional draws represent the posterior variability in ω associated with a randomly selected spool. In Figure 1, we have plotted the median, 0.05, and 0.95 sample quantiles of the 10000 posterior draws in equation (5) as a function of stress s . Note the decreasing trend in the Weibull MTTF as s increases.

Now consider the reliable life for 99% of the population, that is, the 0.01 quantile of the lifetime distribution. The reliable life for 99% of the population distributed according to equation (3) is $\lambda^{-1/\beta} [-\log(0.99)]^{1/\beta}$, which, again upon taking logarithms, substituting equation (4), and simplifying, becomes $-(1/\beta)[\gamma_0 + \gamma_1 \log(s) + \omega + \log(0.99)]$. Thus, for the 10000 joint posterior MCMC draws on β , γ_0 , γ_1 , and σ given t , and a given value of s , the

Figure 1 The median, 0.05, and 0.95 quantiles of the posterior distribution of Weibull $\text{Log}(\text{MTTF})$ as a function of stress s

corresponding posterior draws on $\text{Log}(\text{Reliable life})$ are given by

$$\left\{ \left(\frac{-1}{\beta_\ell} \right) [\gamma_{0\ell} + \gamma_{1\ell} \log(s) + \omega_\ell + \log(0.99)], \ell = 1, \dots, 10000 \right\} \quad (6)$$

In Figure 2, we have plotted the median, 0.05, and 0.95 sample quantiles of the 10000 posterior draws in equation (6) as a function of stress s . For example, at a stress level of 23 MPa, we are 95% certain that 99% of the population should survive at least $e^{4.4} = 81$ h.

Figure 2 The median, 0.05, and 0.95 quantiles of the posterior distribution of Weibull $\text{Log}(\text{Reliable life})$ for $R = 0.99$ as a function of stress s

Summary

Bayesian methods are useful in reliability because of their ease of use (usually *via* MCMC sampling), ability to utilize other sources of relevant information (as prior information), ability to model real-world nuances, and clear probabilistic interpretation.

While hierarchical Bayesian methods place a second-order (hyperprior) distribution on unknown prior distribution parameters, *empirical Bayes* methods (see **Empirical Bayes Estimation of Reliability**) use the observed sampling data to directly estimate these parameters. These parameter estimates are usually produced using either *maximum likelihood* or the *method of moments*. It is generally agreed that empirical Bayes methods provide a good approximation to a full hierarchical Bayesian approach. However, the hierarchical Bayesian approach avoids several issues surrounding empirical Bayes; namely, the double counting of data encountered when estimating the prior parameters and the need to reflect the uncertainties in the estimated prior parameters in the posterior and predictive distributions.

Bayesian Design of Reliability Experiments

Introduction

Reliability is an important criterion in product and system design processes, as described for example in [1]. Engineers use models of various types to predict the reliability of proposed product and system designs. These include probabilistic system reliability models (e.g., [2]) and physical/empirical models such as the Paris law and Miner's rule for fatigue crack growth and finite element models to assess component strength and other physical characteristics. These models require quantitative inputs, which we will call *parameters*. Because of cost and time constraints, it is impossible to use empirical experiments (as distinguished from model-based **computer experiments**) to estimate all of the parameters relating to the reliability of a product or system. Some parameter values are available from vendor specifications, past experience, or from engineering judgment. These parameters are usually known to be within differing amounts of uncertainty, which may or may not be well understood. Sensitivity analysis and the use of engineering "factors of safety" and general conservatism are often used to deal with such uncertainties. When the available information is insufficient for particular components or parts of a system, additional empirical reliability experiments may be required. This need would arise, for example, when new materials or technologies are introduced or when existing components are to be used in new environments. Often, such experiments are censored (i.e., stopping after a fixed time period or a certain fractional failing), and they usually are "accelerated", as described, for example, in [3] and [4, Chapters 17–21].

For example, as described in [5], when testing microelectronic components at increased temperature (**accelerated life test** or ALT using temperature), engineers, if they have understanding of the failure mechanism, will sometimes assume that the activation energy is known. This is equivalent to specifying the slope of the linear relationship between log lifetime and reciprocal absolute temperature (the Arrhenius model). Of course, the activation energy is not known exactly and assuming that it is known gives a false sense of statistical precision. The extremes

(activation energy known exactly vs totally unknown) are illustrated in Figures 1 and 2, taken from an example in Chapter 19 of [4], indicating the large differences in the **estimation confidence intervals** of the failing probability function at use condition (100°C).

From a practical point of view, neither extreme is appropriate. There is, in most applications, useful but imperfect information about activation energy. An appropriate compromise analysis would use a prior distribution to describe the available information and to use Bayesian methods for inference. When planning such a reliability experiment, it is essential to account for the fact that the prior information will be used in the analysis of the experimental results and the prior should also be used in the planning. This can be seen because the optimum plan will be radically different under the two different assumptions (see, for example, [5]). Similar situations arise frequently in applications.

One basic idea of experimental design (Bayesian or not) is to use available knowledge of the process or phenomena to be studied to explore the kind of results that a particular design might produce. This is done by using analytical tools to evaluate important properties of the proposed design such as precision. For example, in non-**Bayesian reliability** testing, a useful metric for assessing a particular experimental design is the large-sample approximate variance of the maximum-likelihood estimator of a specified quantile of the life distribution. Within the Bayesian framework, a similar metric is to compute the expected value of the posterior variance of a quantity of interest, where the expectation is with respect to the data yet to be seen, according to the prior distribution. This is known as *preposterior analysis*.

Some Related Literature

Chapter 6 of [3] and Chapters 10, 20, and 22 of [4] give theory and methods for planning non-Bayesian reliability tests. Classical work in the area of Bayesian design of experiments and preposterior analysis is covered, for example, in [6]. Chaloner and Verdinelli [7] give a broad review of Bayesian design methods. Chaloner and Larntz in [8] and [9] describe Bayesian designs for logistic regression and accelerated testing, respectively. Clyde *et al.* [10] describe the Bayesian

design methods for heart defibrillators, under a logistic regression model. They use a utility function based on preposterior expectation and large-sample approximation for both fixed-point and sequential designs.

Polson [11] describes a general decision theory for the ALT Bayesian design problem and proposes a preposterior expected information-based utility function. Verdinelli *et al.* [12] describe ALT Bayesian

design methods for predictions using utility functions based on Shannon information. Erkanli and Soyer [13] present optimum ALT Bayesian designs for the exponential lifetime distribution with no censoring, by adopting the curve-fitting optimization approaches developed in [14] and [15]. Zhang and Meeker [5] apply Bayesian methods to design an ALT with a log-location-scale distribution and censoring, using preposterior precision on a quantity of interest and large-sample approximation to provide optimum and optimized compromise test plans. Hamada *et al.* [16] show how to find near-optimal Bayesian designs for regression models by using **genetic algorithms**.

The Model

The model and presentation in this article is general, implying wide applicability of the approach outlined here. Suppose that an experiment is to be conducted to estimate the reliability of a product or system under a model that is described by a parameter vector θ of length p . More specifically, suppose that interest centers on a scalar function $g(\theta)$. This, for example, could be the reliability of the system, perhaps at a point in time, if reliability is time dependent. Alternatively, it could be a quantile of the life distribution of the product or the time to first failure of the system.

The prior information on θ is quantified by a joint distribution $\omega(\theta)$ that has a $p \times p$ variance–**covariance** matrix denoted by $\mathbf{S}$. In practice, prior information is usually specified or elicited from an engineer using parameters that are familiar and approximately independent. $\omega(\theta)$ can then be obtained by transformation from these identifiable parameters. Planning results are typically not highly sensitive to the particular shape of the prior distribution.

The Reliability Experiment

There are different types of reliability experiments that can be used to obtain information about θ . For example, [3] describes accelerated life tests and destructive **degradation** tests. Chapter 21 of [4] describes repeated measured degradation tests. The specifics of the model, type of response (e.g., time to failure or degradation), experimental conditions (e.g., temperature levels), **sample size**, and allocation of

the units to the different levels of the experimental variables determine the amount of information (or more precisely, the distribution of the amount of information) that one will get from a proposed experiment. We will let $\mathbf{D}$ denote a particular specified experimental plan.

Quantifying Precision

The expected information from an experimental plan $\mathbf{D}$ can be quantified by a $p \times p$ Fisher information matrix

$$\mathbf{I}_\theta(\mathbf{D}) = \mathbb{E} \left(-\frac{\partial^2 \ell(\theta, \mathbf{D})}{\partial \theta \partial \theta^T} \right) \quad (1)$$

where $\ell(\theta, \mathbf{D})$ is the log likelihood for the model/data combination and T denotes vector transpose. In general, $\mathbf{I}_\theta(\mathbf{D})$ depends on the model and the model parameters. Computing $\mathbf{I}_\theta(\mathbf{D})$ for a given test plan is more complicated when data are censored. Escobar and Meeker [17] describe methods and algorithms for computing $\mathbf{I}_\theta(\mathbf{D})$ for different kinds of censored data.

With a reasonably large sample size, the multivariate **normal distribution** provides a good approximation for the posterior distribution. Then the posterior variance can be expressed as a simple combination of information from the prior distribution and the data. Because $\mathbf{S}$ is the variance–covariance matrix of the prior distribution for θ , $\mathbf{S}^{-1}$ is the prior precision matrix for θ . Then the posterior variance of θ can be approximated by

$$\text{Var}(\theta|\mathbf{t}, \mathbf{D}) \approx [\mathbf{S}^{-1} + \hat{\mathbf{I}}_\theta(\mathbf{D})]^{-1} \quad (2)$$

where $\hat{\mathbf{I}}_\theta(\mathbf{D})$ is $\mathbf{I}_\theta(\mathbf{D})$ evaluated at $\hat{\theta}$, the maximum-likelihood estimator of θ . The posterior variance in equation (2) depends on the test plan $\mathbf{D}$ and the future data $\mathbf{t}$ only through the Fisher information matrix from the experiment.

The posterior variance of $g(\theta)$, the function of interest, can be approximated by

$$\text{Var}(g|\mathbf{t}, \mathbf{D}) \approx (\hat{\mathbf{g}}')^T \text{Var}(\theta|\mathbf{t}, \mathbf{D}) (\hat{\mathbf{g}}') \quad (3)$$

where $\hat{\mathbf{g}}'$ is the gradient vector $\mathbf{g}'(\theta) = \partial g / \partial \theta$, again evaluated at $\hat{\theta}$. Note that the approximate posterior variance in equation (3) depends on the data only through $\hat{\theta}$.

For Bayesian test planning, we need to use the preposterior expectation of $\text{Var}(g|\mathbf{t}, \mathbf{D})$ with respect to

4 Bayesian Design of Reliability Experiments

$\mathbf{t}$ under design $\mathbf{D}$. Taking the expectation with respect to the data is intractable. Instead, following [10], one can use a large-sample approximation,

$$E_{\mathbf{t}|\mathbf{D}}[\text{Var}(g|\mathbf{t}, \mathbf{D})] \approx \int \text{Var}(g|\mathbf{t}, \mathbf{D})_{\hat{\theta}=\theta} d(\omega(\theta)) \quad (4)$$

As explained in [5] the approximation in equation (4) is valid even with moderate-sized samples, when the variability in the prior for θ dominates the sampling variability in its estimates from the data. This integral has the same dimension as θ and for typical reliability experiments its evaluation is more manageable. In particular, if the number of parameters is small (e.g., less than five or six) it can be evaluated by using standard numerical quadrature methods. If the dimension of the integral is large (e.g., in a complicated system with multiple failure modes corresponding to components with different parameters), one could use a **Monte Carlo**-based algorithm to evaluate $E_{\mathbf{t}|\mathbf{D}}[\text{Var}(g|\mathbf{t}, \mathbf{D})]$.

Although it is possible to use other utility functions in the design problem, minimizing the expected posterior variance in equation (4) is meaningful and corresponds to what has been used in previous non-Bayesian design of reliability experiments work.

Design Optimization

There is much work in the literature on optimum design of experiments (e.g., [18] and [19]). The basic ideas used in traditional optimum design area are to optimize some measure of precision (e.g., minimize the variance of an estimator or maximize the determinant of an information matrix), subject to constraints (e.g., number of test units, time, and experimental region). Literature and examples of such optimum plans for non-Bayesian reliability applications are described in Chapter 6 of [3] and Chapter 20 of [4]. Within the Bayesian framework, there is a similar optimization to maximize some Bayes utility such as preposterior precision. Applications in reliability testing include [5, 9, 11–13].

In the area of optimum design, there is a well-known result that for a model that is linear in the parameters, there is an upper bound on the number of design points and that upper bound is equal to the number of parameters in the model. For models that are nonlinear in the parameters, including Bayesian optimum design in nonlinear

problems, the number of design points generally has no theoretical upper bound. This is discussed, for example, in [19, Chapter 19] and [7, Section 5.2]. To confirm that an optimum design has been found one can use a sequential numerical search with different numbers of design points and apply the general equivalence theorem (GET) from [20] to verify the global optimality of a particular plan. Illustrations of this approach are given in [5, 8].

Optimum plans provide useful insight into how to plan an experiment. Such plans, however, have practical deficiencies. For example, they generally provide little **power** to detect departures from the assumed model and they tend to be more sensitive to misspecification of the model and other planning information. Meeker and Escobar [4] illustrate the use of compromise test plans for more **robust design** in non-Bayesian applications. Zhang and Meeker [5] describe and evaluate compromise Bayesian test plans for an accelerated life test experiment.

Prior Distributions

An important (and somewhat controversial) part of Bayesian analysis is the specification of the prior information. When little or no prior information is available, it is common practice to use diffuse or flat **prior distributions**, resulting in an analysis for which the assumed prior is supposed to have no important effect on the posterior distribution and resulting inferences. Various technical difficulties can, however, arise when a diffuse prior distribution is combined with a dataset containing little information.

In preposterior analysis, the prior distribution is used twice – in the computation of the posterior distribution and in the computation of the expected posterior variance of the quantity of interest. Technical problems arise immediately in the preposterior expectation if one attempts to use one single diffuse prior distribution. An alternative approach is to use two different prior distributions. This can be justified because the risk associated with incorrect prior specification may be different for those conducting the experiment and those who will depend on the results of the experiment. This was, in effect, done in [9] with diffuse priors for computing the posterior distribution and informative prior distributions for computing expectations of the quantities of interest.

Empirical Bayes Estimation of Reliability

Introduction

Assessment of the reliability of various types of equipment relies on statistical inference about characteristics of reliability such as reliability function, mean lifetime of the devices, or failure rate. General techniques of statistical inference (estimation and hypotheses testing) are reviewed in **Estimation; Least-Squares Estimation; Maximum Likelihood; Nonparametric Tests; Hypothesis Testing; and Significance Level**, respectively.

Consider the following model. Let $T = (T_1, T_2, \dots, T_m)$, $T_i \in \mathcal{T}$, be independent identically distributed (i.i.d.) observations with the joint **probability density function** (pdf) $f(t|\theta)$, $t \in \mathcal{T}^m$, depending on an unknown parameter $\theta \in \Theta$. If we are interested in estimating θ or a known function $u(\theta)$ of θ , we can, for example, use the maximum-likelihood estimation (MLE) of θ described in **Maximum Likelihood**. This technique is, however, of very little help if we want to accommodate some *prior* information about θ which may be available from previous experiments, expert opinions, or other sources of knowledge. To take advantage of this information, we assume that parameter θ is also a random variable or vector, and the particular value of θ associated with our sample comes from a pool of possible values of θ , which have a *prior* pdf $g(\theta)$. Using Bayes formula one can obtain the updated *posterior* pdf of θ given the sample T as

$$g(\theta|T) = \frac{[f(T|\theta)g(\theta)]}{\left[\int_{\Theta} f(T|\theta)g(\theta) d\theta \right]} \quad (1)$$

The estimator

$$\hat{u}(T) = \int_{\Theta} u(\theta)g(\theta|T) d\theta \quad (2)$$

is called the *Bayes estimator* of $u(\theta)$ and it minimizes the quadratic risk

$$\begin{aligned} R(g) &= E(\hat{u}(T) - u(\theta))^2 \\ &= \int_{\mathcal{T}^m} \int_{\Theta} (\hat{u}(T) - u(\theta))^2 \end{aligned}$$

$$\times f(T|\theta)g(\theta) dT d\theta \quad (3)$$

Here E is the expectation with respect to T and θ (the concept of expectation is introduced in **Expectation**). The prior density $g(\theta)$ is usually chosen from some familiar distribution family, or by some other considerations (to minimize the information introduced by a prior distribution or to make integration in equation (2) easy, etc.). Extensive introduction to Bayesian methods can be found in [1].

In practice, however, none of the choices for the prior may offer sufficient motivation. Moreover, we may have some prior measurements that are indirectly related to the recent data of interest. In particular, suppose that n “past” data sets are available,

$$\begin{aligned} T_i &= (T_{i1}, T_{i2}, \dots, T_{im_i}), \quad T_{ij} \in \mathcal{T}, \\ i &= 1, \dots, n \end{aligned} \quad (4)$$

where, conditional on θ_i , vectors T_i have pdfs $f_i(t|\theta_i)$, and we also have a “present” data set $T = (t_1, \dots, t_m)$, which carries information about the parameter of interest τ . Now, if we assume that $\theta_1, \theta_2, \dots, \theta_n$ and τ are not just fixed constants unrelated to each other but realizations of a random variable with the unknown pdf $g(\theta)$, we can use past data $T_i, i = 1, \dots, n$, for assessment of the value of τ or some function $u(\tau)$ of τ . Decision theoretic procedures that utilize past data as a means for bypassing the necessity of identifying a completely unknown prior distribution are called *empirical Bayes* (EB) decision procedures [2, p. 605].

Empirical Bayes Estimation

Estimator and its Risk

The EB estimation was introduced by Robbins [3] and became increasingly popular in various areas of statistics (see, e.g., [4] and [5] for a general review of EB methods). To simplify our introduction, we consider the case when all conditional densities $f_i(t|\theta)$ are identical and equal to $f(t|\theta)$ (the case of different conditional densities is treated in, e.g., [6]). Let one observe random vectors $(T_1, \theta_1), \dots, (T_n, \theta_n)$, where each θ_i is distributed according to some unknown prior distribution G with the pdf $g(\theta)$ and, given θ_i , T_i has a known conditional density function $f(t|\theta_i)$, $i = 1, \dots, n$. In each pair the first

2 Empirical Bayes Estimation of Reliability

component is observable, but the second is not. For the observation T with the conditional pdf $f(t|\tau)$, the goal is to estimate τ or a function $u(\tau)$. Here (T, τ) can be a new pair of observations $T \equiv T_{n+1}$, $\tau = \theta_{n+1}$, or one of the old ones $T \equiv T_k$, $\tau = \theta_k$, $k = 1, \dots, n$.

If the prior pdf $g(\theta)$ were known, the best estimator for $u(\tau)$ would be the Bayes estimator

$$\hat{u}(T) = \Phi(T)/p(T) \quad (5)$$

where

$$\begin{aligned} \Phi(t) &= \int_{\Theta} u(\theta) f(t|\theta) g(\theta) d\theta, \\ p(t) &= \int_{\Theta} f(t|\theta) g(\theta) d\theta \end{aligned} \quad (6)$$

Here, $p(t)$ is the marginal pdf of T at the point t . As the prior density $g(\theta)$ is unknown, we construct an EB estimator $\hat{u}_n(T) \equiv \hat{u}_n(T; T_1, \dots, T_n)$ as the estimator of the right-hand side of formula (5) based on observations $T_1, T_2, \dots, T_n$. Denote by E_T and E_T the expectations with respect to T and $T_1, \dots, T_n$, respectively. An EB estimator $\hat{u}_n(T)$ can be characterized by its quadratic risk (see [5])

$$R(\hat{u}_n; g) = E_T E_T (\hat{u}_n(T) - u(\tau))^2 \quad (7)$$

which can be partitioned into two components. The first component

$$\begin{aligned} R(g) &= E_T (\hat{u}(T) - u(\tau))^2 \\ &= \inf_v E_T (v(T) - u(\tau))^2 \end{aligned} \quad (8)$$

is the risk of the Bayes estimator, while the second component

$$\hat{R}(\hat{u}_n; g) = E_T E_T (\hat{u}_n(T) - \hat{u}(T))^2 \quad (9)$$

is the error of estimating $\hat{u}(T)$. Robbins [3] called an EB estimator *asymptotically optimal* if $\lim_{n \rightarrow \infty} \hat{R}(\hat{u}_n; g) = 0$.

All techniques for EB estimation can be roughly divided into two classes: *parametric* and *nonparametric*. Parametric methods are based on the assumption that $g(\theta)$ has a known parametric form with one or several unknown parameters. In nonparametric methods, $g(\theta)$ is assumed to be completely unknown and unspecified.

Parametric EB Estimation

Let $g(\theta)$ have a known form with a vector or scale parameter σ , which is unknown: $g(\theta) \equiv g(\theta|\sigma)$. In this case, $\Phi(t)$ and $p(t)$ in formula (6) also have known forms

$$\begin{aligned} \Phi(t) &\equiv \Phi(t|\sigma) = \int_{\Theta} u(\theta) f(t|\theta) g(\theta|\sigma) d\theta, \\ p(t) &\equiv p(t|\sigma) = \int_{\Theta} f(t|\theta) g(\theta|\sigma) d\theta \end{aligned} \quad (10)$$

Hence, the Bayes estimator $\hat{u}(T)$ is a known function $\hat{u}(T|\sigma)$ of σ and T , and the problem reduces to estimation of a parametric function $\hat{u}(T|\sigma)$ on the basis of observations $T_1, \dots, T_n$ with the pdf $p(t|\sigma)$. This is a standard statistical problem. We can, for example, construct the MLE $\hat{\sigma}$ of σ on the basis of observations $T_1, \dots, T_n$ (see **Maximum Likelihood**) and then estimate $\hat{u}(T)$ by $\hat{u}_n(T) = \hat{u}(T|\hat{\sigma})$.

In addition, we can calculate the posterior pdf of θ

$$g(\theta|T, \sigma) = \frac{[f(T|\theta)g(\theta|\sigma)]}{[\int_{\Theta} f(T|\theta)g(\theta|\sigma) d\theta]} \quad (11)$$

and estimate it by $\hat{g}_n(\theta|T) = g(\theta|T, \hat{\sigma})$. We can use $\hat{g}_n(\theta|T)$ for construction of the $(1 - \gamma)$ credibility interval $(\hat{\tau}_l, \hat{\tau}_r)$ for τ by choosing $\hat{\tau}_l$ and $\hat{\tau}_r$ such that

$$\int_{\hat{\tau}_l}^{\hat{\tau}_r} \hat{g}_n(\theta|T, \hat{\sigma}) d\theta = 1 - \gamma \quad (12)$$

(see **Confidence Intervals** for the review of confidence and credibility intervals). The credibility interval for $u(\tau)$ is of the form $(\hat{u}_l, \hat{u}_r)$, where $u(\tau) \in (\hat{u}_l, \hat{u}_r)$ whenever $\tau \in (\hat{\tau}_l, \hat{\tau}_r)$.

Parametric EB estimation is reviewed in [7] and [8] as well as in [4] and [5].

Nonparametric EB Estimation

If $g(\theta)$ is completely unknown, then we can construct a nonparametric estimator of $\hat{u}(T)$. One possible way of doing this is to estimate $g(\theta)$ by $\hat{g}(\theta)$ on the basis of the observations $T_1, \dots, T_n$ and then plug $\hat{g}(\theta)$ into formulae (5) and (6). The first attempt in this direction was to estimate the unobserved parameters θ_i by $\hat{\theta}_i$ on the basis of T_i , $i = 1, \dots, n$, and then use "observations" $\hat{\theta}_i$ for estimation of $g(\theta)$ (see, e.g., [2]). The difficulty, though, is that in order for

$\hat{\theta}_i$ to be consistent estimators of θ_i , the past data should contain series of observations, that is, m_i 's in (4) should be relatively large. This drawback can be avoided by constructing an estimator of $g(\theta)$ directly on the basis of $T_1, \dots, T_n$ (see, e.g., Maritz and Lwin [5] or Walter [9]). However, the shortcoming of any approach that is based on estimating prior density $g(\theta)$ is that estimation of $g(\theta)$ is a much harder task than estimation of $\hat{u}(T)$ itself. Consequently, the risk $\hat{R}(\hat{u}_n; g)$ of the resulting estimator will converge to zero very slowly as $n \rightarrow \infty$.

In order to avoid estimation of $g(\theta)$, one can estimate $u(\tau)$ directly. For example, if $u(\tau) = \tau$ and $f(t|\theta)$ belongs to a one-parameter exponential family

$$f(t|\theta) = w(t)C(\theta)\exp(\theta t) \quad \text{with} \\ u(t) > 0 \quad \text{for } t > a \quad (13)$$

Singh [10] observed that

$$\hat{\tau} = \frac{p'(T)}{p(T)} \quad (14)$$

where $p(t)$ is the marginal density of T defined in formula (6). Note that the gamma and the normal pdfs belong to the family (13).

Estimation of the pdf $p(t)$ and its derivative $p'(t)$ at a point t is a very common problem in statistics and is addressed in a variety of papers and monographs (see, e.g., [11] for a review). One of the possibilities is to construct kernel estimators for $p(t)$ and $p'(t)$

$$\hat{p}_n(t) = \frac{1}{nh} \sum_{i=1}^n K_0\left(\frac{t - T_i}{h}\right), \\ \hat{p}'_n(t) = \frac{1}{nh^2} \sum_{i=1}^n K_1\left(\frac{t - T_i}{h}\right) \quad (15)$$

where h is small and the kernels K_j , $j = 0, 1$, satisfy the conditions $\int t^i K_j(t) dt = 1$ if $i = j$ and $\int t^i K_j(t) dt = 0$ if $i \neq j$, $i = 0, 1, \dots, r$. Here $r \geq 2$ is a positive integer.

The approach of Singh [10] can be generalized as follows (see [6]). Note that in order to construct an EB estimator $\hat{u}_n(T)$ one needs to estimate the numerator and the denominator in formula (5), and then estimate the ratio. The denominator $p(T)$ can be estimated using, for example, the first formula in (15). To estimate the numerator

$\Phi(T) = \int_{\Theta} u(\theta) f(T|\theta) g(\theta) d\theta$ one needs to find a sequence of functions $\varphi_\varepsilon(t)$ such that $\int \varphi_\varepsilon^2(t) dt < \infty$ for every $\varepsilon > 0$ and for every s and θ

$$\int f(t|\theta) \varphi_\varepsilon(s, t) dt - u(\theta) \rightarrow 0 \quad \text{as } \varepsilon \rightarrow 0 \quad (16)$$

Then $\Phi(T)$ can be estimated by

$$\hat{\Phi}_n(T) = n^{-1} \sum_{i=1}^n \varphi_\varepsilon(T, T_i) \quad (17)$$

with small $\varepsilon = \varepsilon_n$. Finding the sequence $\varphi_\varepsilon(s, t)$ may be tricky; however, luckily, in many particular situations, for example, when θ is the location or a scale parameter of the family $f(t|\theta)$,

$$\int_T f(t|\theta) \varphi_\varepsilon(s, t) dt = u(\theta) \quad (18)$$

has an exact solution $\varphi(s, t)$ (see, e.g., [12, 13]).

The last step is estimation of the ratio $\hat{u}(T) = \Phi(T)/p(T)$ by

$$\hat{u}_n(T) = H(\hat{\Phi}_n(T)/\hat{p}_n(T), \delta) \quad (19)$$

where $\delta > 0$ is a small parameter. Here, function $H(a, \delta)$ is chosen to ensure that the overall **mean squared error** tends to zero as n grows: $H(a, 0) = a$ and $H(a, \delta)$ is bounded for any $\delta > 0$. Singh [10] proposed the use of

$$H(a, \delta) = aI(|a|\delta \leq 1) + \delta^{-1}I(a\delta > 1) \\ - \delta^{-1}I(a\delta < -1) \quad (20)$$

where $I(A)$ is the indicator function of the set A . Pensky [6, 12] suggested a smooth version

$$H(a, \delta) = a(1 + \delta|a|^{2\tau})^{-s}, \\ \tau = 1, 2, \dots; \quad s > 0; 2\tau s \geq 1 \quad (21)$$

EB Estimation of the Reliability Function and the Mean Lifetime

Let $T_1, \dots, T_n$ be observations on the lifetimes of the devices of a certain type corresponding to unobserved parameters $\theta_1, \dots, \theta_n$ and let T be a measurement with the pdf $f(t|\tau)$. The general ideas reviewed

4 Empirical Bayes Estimation of Reliability

above can be used for EB estimation of *the mean lifetime*

$$m(\tau) = \int_0^\infty t f(t|\tau) dt \quad (22)$$

and *the reliability function* at a point t_0

$$\begin{aligned} R(\tau, t_0) &= P(T \leq t_0) = \int_0^{t_0} f(t|\tau) dt \\ &= \int_0^\infty I(t \leq t_0) f(t|\tau) dt \end{aligned} \quad (23)$$

For this purpose, one should carry out EB estimation of $u_1(\tau) = m(\tau)$ and $u_2(\tau) = R(\tau, t_0)$ where t_0 is treated as a fixed known constant.

Consider, for example, estimation of the mean lifetime and the reliability function in the case when $f(t|\theta)$ belongs to the family of generalized gamma distributions

$$\begin{aligned} f(t|\theta) &= \frac{\alpha t^{\alpha\nu-1}}{\theta^\nu \Gamma(\nu)} \exp\left(-\frac{t^\alpha}{\theta}\right) I(t > 0), \\ \theta &\in \Theta \end{aligned} \quad (24)$$

where α and ν are known parameters, $\alpha\nu \geq 1$, and the parameter space Θ is a subset of $(0, \infty)$, the positive real line. The family of pdfs (24) includes most of the pdfs used in reliability, for example, the exponential ($\alpha = \nu = 1$), the gamma ($\alpha = 1$), and the Weibull ($\nu = 1$) pdfs. It is easy to calculate that for the family of pdfs (24) we have

$$m(\tau) = \tau^{1/\alpha} [\Gamma(\nu)]^{-1} \Gamma(\nu + \alpha^{-1}) \quad (25)$$

$$R(\tau, t_0) = [\Gamma(\nu)]^{-1} \gamma(\nu, \tau^{-1} t_0^\alpha) \quad (26)$$

where $\gamma(a, x)$ is the incomplete gamma function (see [14, p. 260]).

Parametric EB

Consider an example of parametric EB estimation of $m(\tau)$ and $R(\tau, t_0)$ when $g(\theta)$ is the inverted gamma prior of the form

$$\begin{aligned} g(\theta) &\equiv g(\theta|\sigma) = [\Gamma(\beta)]^{-1} \sigma^\beta \theta^{-(\beta+1)} \\ &\times \exp(-\sigma/\theta) I(\theta > 0) \end{aligned} \quad (27)$$

This prior was considered by many authors, for example, Dey and Kuo [15] and Li [16]. Here, for simplicity, we assume that parameter σ is unknown

while parameter β is known. In this case, the marginal pdf of T is

$$\begin{aligned} p(T) &\equiv p(T|\sigma) = \alpha [B(\nu, \beta)]^{-1} \\ &\times \sigma^\beta T^{\alpha\nu-1} (T^\alpha + \sigma)^{-(\nu+\beta)} I(T > 0) \end{aligned} \quad (28)$$

Hence, the MLE $\hat{\sigma}$ of σ is the value minimizing the likelihood function

$$L(\sigma; T_1, \dots, T_n) = \prod_{i=1}^n p(T_i|\sigma) \quad (29)$$

(see **Maximum Likelihood**) and $\hat{\sigma}$ is the root of the equation

$$\frac{1}{n} \sum_{i=1}^n \frac{T_i^\alpha}{T_i^\alpha + \hat{\sigma}} = \frac{\nu}{\nu + \beta} \quad (30)$$

Therefore, Bayes estimators of $m(\tau)$ and $R(\tau, t_0)$ are given by formulae (5) and (6) with $u_1(\theta) = m(\theta)$ and $u_2(\theta) = R(\theta, t_0)$ (see formulae (25), (26), and (28)):

$$\begin{aligned} \hat{m}(T) &= [\Gamma(\nu)\Gamma(\nu + \beta)]^{-1} \Gamma(\nu + 1/\alpha) \\ &\times \Gamma(\nu + \beta - 1/\alpha) (T^\alpha + \sigma)^{1/\alpha} \end{aligned} \quad (31)$$

$$\begin{aligned} \hat{R}(T, t_0) &= \frac{\Gamma(2\nu + \beta)}{\Gamma(\nu + 1)\Gamma(\nu + \beta)} \frac{t_0^{\alpha\nu}}{(T^\alpha + \sigma)^\nu} \\ &\times F\left(2\nu + \beta, \nu; \nu + 1; -\frac{t_0^\alpha}{T^\alpha + \sigma}\right) \end{aligned} \quad (32)$$

where $F(a, b; c; z)$ is the hypergeometric function (see [14, p. 556]). The EB estimators $\hat{m}_n(T)$ and $\hat{R}_n(T, t_0)$ are obtained by replacing σ with $\hat{\sigma}$ in the expressions (31) and (32). By formula (11), the posterior pdf of τ given T is the inverted gamma

$$\begin{aligned} g(\tau|T, \hat{\sigma}) &= \frac{(T^\alpha + \hat{\sigma})^{\nu+\beta}}{\tau^{\nu+\beta+1} \Gamma(\nu + \beta)} \\ &\times \exp\left(-\frac{(T^\alpha + \hat{\sigma})}{\tau}\right) \end{aligned} \quad (33)$$

and the **confidence intervals** for τ are of the form (12).

Nonparametric EB

Now, let us consider nonparametric EB estimation of $m(\tau)$ and $R(\tau, t_0)$. In this subsection, following [17],

we carry out EB estimation under the assumption that θ belongs to some interval: $\Theta = [a_1, a_2]$, $0 < a_1 < a_2 < \infty$ where a_1 and a_2 are unknown. The problem reduces to estimation of $\hat{m}(T) = \Phi(T)/p(T)$ and $\hat{R}(T, t_0) = \Psi(T)/p(T)$ where $\Phi(T)$ and $\Psi(T)$ are of the form (6) with $u_1(\theta) = m(\theta)$ and $u_2(\theta) = R(\theta, t_0)$ given by formulae (25) and (26), respectively. Denote

$$Q(z, \varepsilon) = [\Gamma(1/\alpha)]^{-1} z^{1/\alpha-1} - (\varepsilon z)^{(1/\alpha-1)/2} J_{1/\alpha-1} \left(2\sqrt{z/\varepsilon} \right) \quad (34)$$

where $J_b(\cdot)$ is the Bessel function of integer order (see [14, p. 360]). Estimate $\Phi(T)$ and $\Psi(T)$, respectively, by

$$\begin{aligned} \hat{\Phi}_n(T) &= n^{-1} \sum_{j=1}^n \varphi_\varepsilon(T, T_j), \\ \hat{\Psi}_n(T, t_0) &= n^{-1} \sum_{j=1}^n \psi(T, T_j, t_0) \end{aligned} \quad (35)$$

with

$$\varphi_\varepsilon(T, T_j) = \begin{cases} \alpha T^{\alpha v-1} \frac{T_j^{\alpha-\alpha v} (T_j^\alpha - T^\alpha)^{1/\alpha-1}}{\Gamma(1/\alpha)} & \text{if } 0 < \alpha < 4/3 \\ T^{\alpha v-1} T_j^{\alpha-\alpha v} Q(T_j^\alpha - T^\alpha, \varepsilon), & \text{if } \alpha \geq 4/3 \end{cases} \quad (36)$$

and

$$\begin{aligned} \psi(T, T_j, t_0) &= \frac{\alpha T_j^{\alpha-\alpha v} T^{\alpha v-1} (T_j^\alpha - T^\alpha)^{2v-1}}{\Gamma^2(v)} \\ &\times B\left(\frac{t_0^\alpha}{T_j^\alpha - T^\alpha}; v, v\right) \\ &\times I(t_0^\alpha \leq T_j^\alpha - T^\alpha) \end{aligned} \quad (37)$$

Here $B(A; v, \mu)$ is the incomplete beta function (see [14, p. 263]), $\varepsilon = 2(\ln n \ln \ln n)^{-1}$. Estimate $p(T)$ by $\hat{p}_n(T)$ (see formula (15)) with

$$K_0(x) = (-x)^{-1/2} J_1 \left(2\sqrt{-x} \right) I(x < 0) \quad (38)$$

with $h = 2(\ln n \ln \ln n)^{-1}$. Finally, choose $H(a, \delta) = aI(0 < a\delta \leq 1) + \delta^{-1}I(a\delta > 1)$ and estimate $\hat{m}(T)$ and $\hat{R}(T, t_0)$ by $\hat{m}_n(T) = H(\hat{\Phi}_n(T)/\hat{p}_n(T), \delta)$ and $\hat{R}_n(T, t_0) = H(\hat{\Psi}_n(T)/\hat{p}_n(T), \delta)$, respectively.

EB Estimation of the Failure Intensity Function

Consider a repairable system and let $T = (t_1, \dots, t_m)$ be its failure times. The number of failures $N(t)$ during time interval $[0; t]$ is commonly described by the Poisson distribution

$$\begin{aligned} P(N(t) = k) &= [\Lambda(t)]^k \exp(-\Lambda(t)) / k!, \\ k &= 0, 1, 2, \dots \end{aligned} \quad (39)$$

Here, $\Lambda(t)$ is the average number of failures during time interval $[0; t]$, and $\lambda(t) = \Lambda'(t)$ is the *failure intensity function*. It is known (see, e.g., [18]) that in this situation the joint pdf of $t_1, \dots, t_m$ is of the form

$$f(t_1, \dots, t_m) = \left(\prod_{i=1}^m \lambda(t_i) \right) \exp\{-\Lambda(t_m)\} \quad (40)$$

The main concern of a practitioner is the behavior of the failure intensity $\lambda(t)$: whether it is increasing, decreasing, or staying constant. It is common in reliability to work with the *power law processes* with the intensity function of the form

$$\lambda(t) = \theta \beta t^{\beta-1}, \quad t > 0 \quad (41)$$

Here, β is the growth parameter, so that $\lambda(t)$ is increasing if $\beta > 1$, decreasing if $\beta < 1$, and equal to a constant failure rate $\lambda(t) \equiv \lambda$ if $\beta = 1$. The value of β can be estimated on the basis of the sample T but the estimator is not reliable when m is small.

Now, consider the situation when one observes failure times of n **repairable systems** $T_i = (T_{i1}, T_{i2}, \dots, T_{im_i})$, $i = 1, \dots, n$, where the i th system has an intensity function of the form equation (41) with parameters θ_i , and a common parameter β . Using EB approach reviewed above, one can use these past data for estimation of the intensity function $\lambda(t) = \tau \beta t^{\beta-1}$ corresponding to data $T = (t_1, \dots, t_m)$. Following [18], we assume that $\theta_1, \dots, \theta_n, \tau$ have the gamma prior pdf

$$\begin{aligned} p(\theta|a, b) &= [\Gamma(a)]^{-1} b^a \theta^{a-1} \exp(-b\theta), \\ \theta &> 0 \end{aligned} \quad (42)$$

where hyperparameters a and b are considered fixed but unknown. Hence, the marginal pdf of

$\mathbf{T} = (T_1, T_2, \dots, T_n)$ is of the form (see [18], p. 223)

$$p(T_1, \dots, T_n | a, b, \beta) = \beta^M \frac{b^{an}}{[\Gamma(a)]^n} \left(\prod_{i=1}^n \prod_{j=1}^{m_i} T_{ij} \right)^{\beta-1} \times \prod_{i=1}^n \frac{\Gamma(n_i + a)}{(T_{im_i}^\beta + b)^{m_i+a}} \quad (43)$$

where $M = \sum_{i=1}^n m_i$. Parameters a , b , and β can be found by the MLE procedure. In the general situation, MLEs of a , b , and β cannot be expressed explicitly; however, if for all n systems the values of T_{im_i} are identical and equal to s , then the MLE $\hat{a}$ of a is the solution of the equation

$$\sum_{i=1}^n \sum_{j=1}^{m_i} \frac{1}{\hat{a} + j - 1} = n \ln \left(1 + \frac{M}{n\hat{a}} \right) \quad (44)$$

while the MLEs $\hat{\beta}$ and $\hat{b}$ of β and b have, respectively, the following forms

$$\hat{\beta} = M \left(\sum_{i=1}^n \sum_{j=1}^{m_i} \ln(s/T_{ij}) \right)^{-1}, \quad \hat{b} = n\hat{a}s^{\hat{\beta}}/M \quad (45)$$

The posterior pdf of τ is then of the form

$$p(\tau | T) = \frac{(t_m + \beta)^{m+\hat{a}} \tau^{m+\hat{a}-1}}{\Gamma(m + \hat{a})} \exp(-\tau(\hat{b} + t_m^{\hat{\beta}})) \quad (46)$$

and can be used for point or interval estimation of τ .

Discussion

EB estimation of reliability was carried out by a number of researchers in the last 40 years. Martz and Waller ([2], Chapter 13) and Attia [19] offer a review of the techniques on the EB approach to reliability which complements this article.

Parametric EB estimation of the mean lifetime and the reliability function was considered in [15, 16, 20–23] among others. Dey and Kuo [15] investigated EB estimation of the mean lifetime for Weibull distribution with type II censored data, while Li [16] treated the case when $f(x|\theta)$ belongs to the exponential family. Both Dey and Kuo [15] and Li [16] employed the (inverted) gamma prior. Abu-Salih *et al.* [20] and Chiou [22] studied EB estimation of the reliability function in the case of the exponential

distribution, Ahsanullah and Ahmed [21] for a special class of distribution families, Jaheen [23] in the case of the Burr type X distribution, and Padgett [24] in the case of the lognormal model.

Various authors were involved in nonparametric estimation of reliability function and mean lifetime, see, for example, [17, 25–28] among others. For instance, Nakao and Liu [27], Papadopoulos [28], and Sarhan [29] estimated θ_i from previous data $T_i = (T_{i1}, T_{i2}, \dots, T_{im_i})$ and then constructed a nonparametric estimator $\hat{g}(\theta)$ of $g(\theta)$ using estimators $\hat{\theta}_i$ as “observations”. Lahiri and Park [25] and Liang and Padgett [26] carried out nonparametric EB estimation of the mean lifetime and the reliability function, respectively, based on **Dirichlet process** prior. The concept of nonparametric Bayes and EB estimators based on Dirichlet process prior is reviewed systematically in, for example, [30]; however, it is too mathematically involved to be treated in this small article. Finally, Pensky and Singh [17] used the approach based on estimating the numerator and the denominator of the Bayes estimator reviewed above. In addition, Liang and Singh [31] carried out EB testing for the value of the mean lifetime [32] and the reliability function [31].

EB estimation of the failure rate was studied in [33–36], and [18]. Gupta and Liang [33] used nonparametric EB approach for selecting the most reliable Poisson population, that is, the population with the smallest failure rate. Li [34] studied admissibility of EB rules for different types of priors. Mazzuchi and Soyer [35] estimated **software failure** rate when the life length of software on each stage of testing is described by exponential distribution and failure rates λ_i have the gamma pdfs. Finally, Rigdon and Basu provided extensive treatment of the EB estimation of the failure intensity function in their book [18].

MARIANNA PENSKEY

Maintenance and Markov Decision Models

Introduction

Maintenance modeling and Markov decision chains (MDCs) have a large joint history. For both areas the main research started in the 1950s. They formed a fruitful partnership, with theory allowing applications and applications guiding the need for theoretical developments. In this chapter we sketch the main ideas behind MDCs and indicate how they are applied in the maintenance area. In particular, we treat the area of maintenance of civil structures. Apart from providing ample references, we state the pros and cons of the Markov decision modeling.

Historical Perspective

Intense scientific interest in problems related to maintenance management originated only a few decades ago. The basis for the scientific support of maintenance is found in reliability engineering. The book *Mathematical Theory of Reliability* (Barlow and Proschan [1]) indicates the start of scientific interest in maintenance problems. In the early stages, maintenance was almost exclusively interpreted as preventive replacement of components (*see Replacement Strategies*). The development of some simple but insightful models describing aging phenomena of technical components, as well as the choice of appropriate actions to cope with these phenomena, showed that a scientific approach could be useful. One such model is the MDC. In the 1970s and early 1980s, the basic models were extended in several directions. In the 1980s, scientists made a step forward in bridging the gap between the analytical models and practice by a systematic analysis of systems. Moreover, similar to many other areas of applied (stochastic) optimization, the major advances in information technology brought the use of quantitative analytic models within computational reach.

During the last 15 years, substantial progress has been made in developing quantitative decision support systems for maintenance management of complex systems. Sophisticated decision support systems are in operation nowadays in the oil industry (both

for maintenance of refineries as well as offshore installations), the civil infrastructure sector (road, bridges, and railway), and electric power generation. The number of organizations that make use of some kind of quantitative tools to support inspection and replacement of equipment is increasing rapidly.

Maintenance

Maintenance can be defined as the combination of all technical and associated administrative actions intended to retain an item or system in, or restore it to, a state in which it can perform its required function. The maintenance objectives can be summarized under four headings – ensuring system function (availability, efficiency, and product quality); ensuring system life (asset management), ensuring safety, and ensuring human well-being.

For production equipment, ensuring the system function is often the prime objective. Here, maintenance has to provide the right (but not the maximum) reliability, availability, efficiency, and capability (i.e., producing at the right quality) of production systems in accordance with the need for these characteristics. In principle it is possible to give an economic value to the maintenance results, and a cost balance can be done. Ensuring system life and asset management refers to keeping systems as such in proper condition, while there are only indirect links to a possible production of goods or services. This objective is appropriate for civil structures like buildings, dams, offshore platforms, and roads, as their function is complex and not easy to measure. Often norms have to be set to define failure, and the benefits of maintenance are therefore more difficult to quantify. In this case, one has to minimize maintenance costs to meet the norms or conditions on states. Safety plays a role, as failures can have dramatic consequences, e.g., in the case of airplanes, and nuclear and chemical plants. In this case, testing and inspection activities constitute an important part of the maintenance work. Here, costs of maintenance have to be minimized while keeping the risks within strict limits and meeting statutory requirements. Finally, we refer to human well-being or shine as an objective; though there is no direct economic or technical necessity, it has primarily a psychological one (which indirectly may be economical). An example is painting, which is not done for protective reasons.

2 Maintenance and Markov Decision Models

Many models for maintenance consider replacing of parts or systems. Typical models are the age- and block-replacement models (*see Multivariate Age and Multivariate Renewal Replacement*). These models consider only one state of the system, *viz* working or failed. Next to that there are condition-based models that consider multiple states and these can be modeled by MDCs. For mechanical equipment, deterioration can be quick, and the economic importance of failures can be clear. In the case of civil infrastructures, deterioration can be very slow, and failure does not always have direct economic consequences. As a result, it is much more important to decide when to do maintenance for such systems and to allocate the budget to those assets with the highest needs. Markov decision models can be helpful in this respect.

Markov Decision Models

A Markov model is a special type of dynamic model with which the probabilistic evolution of a system can be modeled in time. The main assumption underlying such a model is that all information about the future behavior is captured in the state description. In other words, the present state provides all relevant information about the future behavior, and knowledge about previous states is not necessary. More formally, a Markov chain is a discrete-time process governed by a discrete state space E (observed at discrete time points) and transition matrix P , for which the Markov property holds, *i.e.*,

$$\begin{aligned} P_{ij} &= P(X_{t+1} = j | X_0 = i_0, X_1 = i_1, \dots, X_t = i) \\ &= P(X_{t+1} = j | X_t = i) \end{aligned} \quad (1)$$

If the transition probabilities do not depend on t , then the Markov chain is said to be stationary. An MDC is an extension of a Markov chain, where the Markov chain can be steered by actions and with which optimal actions can be determined. An alternative name is *Markov decision process* as it basically describes a stochastic process. The term *chain* is used to indicate that it gives rise to a chain of states in time. It is defined by a four-tuple E, A, P , and r – where E denotes the state space; $A(i)$ the action set in state $i \in E$; $P_{ij}(a)$, $i, j \in E$ the transition probabilities; and $r_i(a)$, $i \in E$, $a \in A(i)$, the immediate rewards in state i when action a is chosen.

The control is defined through policies and decision rules. A policy π is a sequence of decision rules $(\pi^1, \pi^2, \dots)$ where π^t is a function that assigns to each action a the probability of that action being taken at time t . For a memoryless or Markov policy, the decision rule at time t is independent of the states and actions before time t . A policy is said to be stationary and deterministic if all decision rules are identical and nonrandomized. For any decision rule π , we denote by $P(\pi)$, $r(\pi)$ the matrix and the vector with $P_{ij}(\pi(i))$ and $r_i(\pi(i))$ as i th element, respectively. Let $P^k(R) = P(\pi^k) \dots P(\pi^1)$ and $P^0(R) = I$, the identity matrix. The evolution of the MDC under a given stationary and deterministic policy f is a Markov chain with transition probability matrix $P(f)$. Let C be the class of all policies and C_M be the class of Markov policies. In policy optimization the issue is to find the best action a in each state such that some criterion is optimized. The expected total α -discounted rewards are defined by

$$v^\alpha(R) = \sum_{k=0}^{\infty} \alpha^k P^k(R) r(\pi^{k+1}) \quad (2)$$

Here α is the discount factor, which is taken from $[0, 1)$. For a stationary policy f , one can also obtain the discounted rewards $v^\alpha(f)$ by solving a set of equations, *i.e.* (in vector notation)

$$v^\alpha(f) = r(f) + \alpha P(f) v^\alpha(f) \quad (3)$$

Again if $\alpha < 1$, this set has a unique solution. Note that the size of this set of equations is equal to the size of the state space. Normally solving such a set takes a number of operations, which increases with the cube of the size of the state space. A policy R_α is called α -discounted optimal if for all $i \in E$, $R \in C$ we have

$$v_i^\alpha(R_\alpha) \geq v_i^\alpha(R) \quad (4)$$

A second criterion is the long-run expected average rewards, defined by

$$g_i(R) = \liminf_{N \rightarrow \infty} \frac{1}{N+1} \sum_{k=0}^N \sum_{j \in E} P_{ij}^k(R) r_j(\pi^{k+1}) \quad (5)$$

Let $g_i^* = \sup_{R \in C} g_i(R)$. In the finite-state and finite-action case, there exists an average optimal policy and the supremum can be replaced by a maximum. In the case of a denumerable state space, an

average optimal policy may exist only under certain conditions (like unichain and a certain recurrence). A policy R is long-run average optimal if $g_i(R) = g_i^*$, for all $i \in E$. For both criteria it can be shown that one can restrict oneself to the class of Markov policies. The first step in optimization is the derivation of the so-called optimality equations. For the α -discounted rewards they are defined as follows:

$$v_i^\alpha = \max_{a \in A(i)} \left\{ r_i(a) + \sum_{j \in E} \alpha P_{ij}(a) v_j^\alpha \right\}, \quad i \in E \quad (6)$$

It appears that there exists a unique solution to them and that any policy that takes maximizing actions in each state is α -discounted optimal. The optimality equations for the long-run average costs consist of two equations, viz

$$g_i = \max_{a \in A(i)} \left\{ \sum_{j \in E} P_{ij}(a) g_j \right\}, \quad i \in E \quad (7)$$

$$g_i + v_i = \max_{a \in A^0(i)} \left\{ r_i(a) + \sum_{j \in E} P_{ij}(a) v_j \right\}, \quad i \in E \quad (8)$$

$$\text{where } A^0(i) = \left\{ a \in A(i) \mid g_i = \sum_{j \in E} P_{ij}(a) g_j \right\}$$

Again a solution g, v to this set of equations is unique up to a constant vector for v and the solution g equals g^* . Any policy that takes maximizing actions in both equations in all states is average optimal. These equations can be simplified in case the MDC is *unichain* (which means that under all policies the Markov chain has one minimal closed set) or even weaker, if it is *communicating*, i.e., for every two pairs of states i and j , there is a policy f such that $P_{ij}^k(f) > 0$ for some $k > 0$. In this case the optimal average reward vector is a constant vector g and the first equation in the optimality equation is automatically satisfied. The next problem is to solve the equations.

Solution Methods

In principle there are three solution methods, i.e., policy improvement (PI), value iteration, and linear

programming (LP). PI works with a starting policy f_0 and determines in each step for each state an improving action. It appears that the stationary policy belonging to these actions also improves the objective function. As there are only a finite number of policies, the algorithm is finite. An algorithm for the α -discounted rewards is as follows:

- Step 0: let $k = 0$ and choose a starting policy f_0 .
- Step 1: policy evaluation: determine $v^\alpha(f_k)$ from equation (3).
- Step 2: PI: determine for each state $i : \max_{a \in A(i)} r_i(a) + \alpha \sum_{j \in E} P_{ij}(a) v_j^\alpha(f_k)$. Let $f_{k+1}(i)$ be the policy consisting of the maximizing action for each state i . Choose $f_{k+1}(i) = f_k(i)$ when possible.
- Step 3: if $f_{k+1} = f_k$, then stop, else increase k by 1 and return to step 1.

The successive approximation algorithm works with value iteration. It tries to find a solution to the optimality equations by repeatedly evaluating them. An algorithm is as follows:

- Step 1: choose a starting vector $v_i^0, i \in E$, e.g., by taking $v_i^0 = \max_{a \in A(i)} r_i(a)$ and set $k = 0$.
- Step 2: let $v_i^{k+1} = \max_{a \in A(i)} r_i(a) + \alpha \sum_{j \in E} P_{ij}(a) v_j^k, i \in E$.
- Step 3: check if $|v_i^{k+1} - v_i^k| < \varepsilon$ for all $i \in E$, if not go back to step 2.
- Step 4: determine the policy that takes maximizing actions in the last step.

The resulting policy has α -discounted rewards, which differ by less than $2\alpha(1 - \alpha)^{-1}\varepsilon$ from the maximal α -discounted rewards. The algorithm may be speeded up by eliminating nonoptimal actions. It is faster than PI if the transition matrix is sparse and only few transitions are possible. Finally the LP approach consists of formulating an LP for the optimality criterion. One can prove the following formulation

$$\begin{aligned} & \min \sum_{j \in E} \beta_j v_j, \\ & \text{s.t. } v_i \geq r_i(a) + \alpha \sum_{j \in E} P_{ij}(a) v_j, \quad a \in A(i), i \in E \end{aligned}$$

where $\beta_j, j \in E$, is just a vector of positive components. The solution equals the optimal discounted

rewards, and the policy consisting of actions that are binding in the LP restrictions is α -discount optimal. The advantage is that standard LP solvers can be used. From the LP formulation it follows that an MDC can be solved in polynomial time. More complex results are given in Papadimitriou and Tsitsiklis [2].

Issues in Applying MDCs

In general, there are two problems with applying the Markov decision model. The first is identifying states and establishing the Markov property and the second, which is related to the first, is the issue that state spaces can be very large, with the consequence that computation times can be prohibitive.

New techniques concentrate on finding a functional form for the value function. Remember that if one has an approximation for the value function, one can apply the PI step from the PI algorithm to obtain a better- or near-optimal policy. Several approaches have been suggested to this end. We would like to mention neurodynamic programming from Bertsekas and Tsitsiklis [3], reinforcement learning from Das *et al.* [4] and simulation-based approaches by Marbach and Tsitsiklis [5].

Extensions of the Markov Decision Chain Model

In a *semi-MDC* the time between observations of the system is not only fixed, but it is also a random variable, with a distribution that depends on the state and action chosen. Most parts of the analysis can be extended to semi-Markov chains. It is also possible to define a corresponding discrete-time Markov chain, by discretizing the transition time distribution, but this does increase the state space considerably.

In a *continuous-time Markov process*, the time between consecutive transitions is exponentially distributed. These **Markov processes** can be converted into discrete-time Markov chains. We refer to **Markov Processes** for an extensive treatment of Markov processes.

In a *partially observable MDC*, the problem is that not all states are observable and hence no specific actions can be taken once the system enters these states. A separate branch of theory is devoted to these types of Markov chains. A problem is that it

is no longer optimal to restrict oneself to Markov policies, because information on the past history also plays a role. This makes both analysis and solution methods inherently more difficult. Overviews on this type of models have been given by Monahan [6] and Lovejoy [7].

MDC Applications to Maintenance Problems

Maintenance problems have been among the first applications of MDCs, as the model allows both the modeling of the deterioration as well as the determination of the structure of optimal policies. Early examples were given by Sasieni [8] and Howard [9] in his car replacement problem. Let us describe the latter.

Consider a car, the age of which is expressed in periods of 3 months; so an age of j indicates an age of $3j$ months. In every period, the car could either age with another period or have a catastrophic failure/accident after which it is replaced with another car. Instead of letting the car age, we can also decide to replace it preventively with another car. In both cases, one needs to choose what kind of age the replacement car should have. The system can be modeled by taking the present age of the car as a state. Transitions to other states occur because of either the aging of the car or a catastrophic failure, in which case we replace the car. From a lifetime distribution, the transition probabilities can be derived. Next we need the cost figures for operating (e.g., due to some small maintenance), for failures, and for acquiring a car of a certain age j , for all values of j . We would like to remark that in the Markov chain modeling with expected rewards criteria, we do not need to bother whether costs were actually incurred before or after a transition. One just takes an expectation over all possible transitions in a state to define the expected immediate rewards. One of the results of MDC theory is that the optimal policy is of the control-limit type, i.e., replace the car if its age is beyond a critical age threshold. This can be proved by showing that the α -discounted costs increase in the states. Other approaches would not give such results.

The Markov decision approach has particularly been followed in condition-based maintenance, where different conditions of equipment are considered and maintenance actions are based on these. Next, there are many studies in maintenance that make use of

Markov models (*see Markov Processes*), but they use other methods to optimize rather than Markov decision theory.

Real applications have been very much in the sector of civil infrastructure, *viz* roads, bridges, and buildings. Nice overviews of applications have been given by Hontelez *et al.* [10] and Frangopol *et al.* [11]. Applications in other maintenance areas are less common, and as an example we would like to mention Amari *et al.* [12] for inspection planning of condition-based maintenance and Stengos and Thomas [13], who consider the replacement of blast furnaces in a steelworks. It appears that preventively replacing both the furnaces at the same time is not beneficial and that a specific cycle should be followed to reduce the probability that both furnaces fail together. In general, there are two different ways to model states. In the first, one takes the age of a structure as central and takes that as the basis to derive transition probabilities. An alternative is that one takes the remaining life span as a state. In the other modeling, one classifies the condition of the object according to some scale. Table 1 below shows a classification given by Scherer and Glagola [14] for bridge components.

Van Winden and Dekker [15] also use such a condition scale, albeit with five levels. These conditions are typically identified on inspection by classified personnel. One problem however with such scales is that the time to transition is not constant and that a semi-Markov modeling should be used. The latter can be converted by taking the residence time as an extra state variable, but it would make the state space two dimensional.

Another practical issue is that often the state of multiple components or different deterioration mechanisms has to be taken into account. Van Winden and Dekker [15] consider various elements in a building,

like window frames, masonry, pointing, and painting. Dekker *et al.* [16] consider for a road segment longitudinal and transversal unevenness, cracking, and raveling. All these aspects can be modeled but they make the state space multidimensional. A decomposition is not always possible because there can be actions which address multiple deterioration aspects or multiple components and which are cheaper than addressing these components separately.

The final issue is that often multiple objects need to be considered, because of either economies of scale in maintenance or budget restrictions that allow only some maintenance to be carried out. We now would like to discuss approaches for roads, bridges, and buildings.

A seminal paper on road maintenance was published by Golabi [17] and it discusses a pavement maintenance system for Arizona's highways. In the system the whole state highway system was modeled. LP was used as the technique; it has the advantage that restrictions on the fraction of road segments in a certain state can be taken into account. A problem is that no costs are involved with bad states; so one has to find a driver to stay out of these states. A special modeling advantage of roads is that they are more or less similar objects and that large sums of money are involved in their maintenance. The disadvantage is that one needs to consider road segments of 100 m and build up a quite large state space. The MDC approach is typically split 1 into several phases. First for a single segment, a Markov decision model is formulated and an optimal policy is derived. From this policy it follows what kind of budget is needed to keep the road in a good condition. Next one considers a whole network of road segments and determines priorities to work on the segments in case the budget is restricted. The advantage of this approach is that the state of all the highways can be

Table 1 Condition state descriptions^(a)

Condition state	Description
9	New condition
8	Good condition: no repairs needed
7	Generally good condition: potential exists for minor maintenance
6	Fair condition: potential exists for major maintenance
5	Fair condition: potential exists for minor rehabilitation
4	Marginal condition: potential exists for major rehabilitation
3	Poor condition: repair or rehabilitation required immediately

^(a)© American Society of Civil Engineers, 1994

taken into account, which gives a much fairer budget allocation. Many papers extended this approach, e.g., Chen *et al.* [18], Abaza and Ashur [19], Bako *et al.* [20], and Dekker *et al.* [16]. Later on, pavement management systems using Markov decision models came into use in many US states and other countries.

For bridges, the first paper was written by Scherer and Glagola [14], who have investigated the applicability and discussed the problems to keep the state space limited. The first real application, Pontis, was again made by a team led by Golabi [21]. Later on more applications followed (see Hawk and Small [22]). A problem with bridges, compared to roads, is that the bridges are more or less unique, which makes the modeling quite time consuming.

Building maintenance can be approached in a way similar to bridge maintenance. One trick with buildings is that one can work with generic elements and determine policies for these. Next an upscaling is made. For example, pointing is measured in square meters and the total costs can be determined by considering the total number of square meters per building multiplied by the cost per square meter. Sometimes a subdivision is necessary, but otherwise most of the same parts have a similar aging. This limits somewhat the number of components in a building, but considering a whole inventory of the building does give a large state space. One of the interesting results of MDC in this respect is that a trade-off between quality and costs can be obtained, which facilitates decision making, as shown in Figure 1, derived by Van Winden and Dekker [15]. Again, this is difficult to achieve with other techniques.

Finally we would like to mention quite a few papers on partially observable MDCs and maintenance. Again this is a natural combination as quite

often deterioration is not visible, but it can be modeled. Frangopol *et al.* [11] give a number of examples for bridge maintenance.

A natural extension of these is the application of MDCs in health maintenance. Here again the modeling is on the evolution of a disease within a human with several stages. The MDCs are used to determine the effectiveness of early screening for diseases and an example is Singer [23].

Conclusions

Markov decision chains have been a very successful tool in modeling maintenance. As such they are the main models in civil infrastructure maintenance. The main problem lies however in the size of the state space. But new techniques allow for much larger state spaces. So far no real alternative models have emerged which allow the determination of optimal policies. Hence, the main future issue is to develop new techniques to tackle the large multidimensional state spaces.

Prior Distribution Elicitation

Introduction

Expert engineering judgment plays a vital role in assessing and modeling the quality and reliability of systems [1, 2], although presenting subjective judgments as formal probability distributions is not without controversy [3]. Like any **data collection** process, a sound methodology for elicitation is a prerequisite for acquiring reliable subjective expert judgment, which will be summarized in the form of a prior distribution.

A prior distribution is a subjective probability distribution describing some unknown quantity of interest that has been elicited from a relevant person(s) prior to observing data. Using Bayes theorem, the prior distribution is updated in the light of data to produce a posterior distribution. Updation requires a conditional probability distribution, known as the *likelihood function*, which describes the probability of observing the data conditional on the state of the unknown quantity of interest.

A subjective probability distribution is one that describes a person's belief in the value of an unknown quantity. Winkler [4] believes that there is no single correct subjective probability distribution for an unknown quantity because each person forms his/her beliefs from personal experience. Cooke [5] points out that there is no way of measuring the correctness of a subjective distribution. In contrast, O'Hagan [6] distinguishes between true and stated probabilities. The former would result if an expert were capable of perfectly accurate assessments, while the latter would result from attempts to specify the underlying true probabilities. The authors agree that a good prior distribution will conform to the laws of probability, although the differing perspective has implications for validation.

The Bayes coherency principal states that uncertainties are described by probabilities and subjective probabilities should be such as to ensure self-consistent betting behavior [7]. This means that a person assesses subjective probabilities in such a way that they would avoid gambles involving certain losses (a so-called Dutch book). In principle, subjective probabilities can be measured

through preference behavior, when a subject declares indifference between the event under discussion and a lottery with a known probability (assuming of course that the "prizes" are comparable).

Even if a prior distribution conforms to the laws of probability, some elicited distributions provide more useful inference than others. Research in experimental psychology has demonstrated that accurate subjective probabilities are unobtainable by simply asking someone to provide a probability number; instead a structured elicitation process is required [8, 9]. These processes consist of an "expert" (or set of experts) and an "analyst". Following the definition of Ferrell [10], an expert is "a person with substantive knowledge about the events whose uncertainty is to be assessed", while an analyst should be a suitably qualified individual who will collect the data from the expert in order to formulate the prior distribution for use in modeling. The aim of an elicitation process is to minimize the impact of biases inherent in surfacing and capturing subjective expert judgment.

After examining aspects of modeling relevant to the elicitation of a prior distribution in the section titled "Model Parameterization and Uncertainties", the section titled "Heuristics and Biases" describes the typical biases encountered during elicitation. The section titled "Assessing Prior Distributions" further considers characteristics of good prior distributions, while the section titled "Improving Probability Assessors" highlights issues associated with improving the ability of assessors to provide useful inference. The section titled "Generic Processes" outlines a generic process for supporting the elicitation of a prior distribution and provides references to specific processes used in reliability. Finally, the section titled "Summary and Conclusions" reflects upon advanced theoretical and practical issues concerning the elicitation of prior distributions.

Model Parameterization and Uncertainties

It is useful to distinguish between different types of uncertainty in modeling: aleatory uncertainty, which corresponds to inherent randomness in the process generating observations; and epistemic uncertainty, which corresponds to state of knowledge of an expert. Within a Bayesian statistical model, the aleatory uncertainty is described by the likelihood

function, while the prior distribution describes the epistemic uncertainty. Typically, as more relevant data are acquired, the epistemic uncertainty is reduced although the aleatory uncertainty is not. As an example, consider the uncertainty associated with determining the length of time a component will operate without failing. The uncertainty associated with the mean time to failure of a component from a particular class is epistemic and will reduce through observing the times to failure for such components. However, even if the mean time to failure of components within this class is known, the aleatory uncertainty would still remain with respect to the actual time to failure for any one component.

Many of the favored model parameters, such as a failure rate and mean time to failure, are not actually observable quantities, but are simply parameters of a model used to make predictions about the future. It has been strongly argued on foundational grounds, for example the discussion in Chapter 2 of Bedford and Cooke [11], that an expert should only be asked for probability assessments on observable quantities. This raises an interesting issue concerning the degree to which the model construct relates to an expert's perception and hence the coverage of the elicitation. For example, Bedford *et al.* [2] propose that elicitation should include qualitative structuring of the model as well as the quantitative assessment of the prior distribution for the quantity of interest to facilitate appropriate parameterization.

Heuristics and Biases

Research in psychology is relevant to the elicitation of a prior distribution. The identification of the major sources of bias within expert assessments motivates the need for supportive elicitation processes and validation of data.

Sunstein [12] discusses two alternative cognitive systems to describe how a person makes decisions: System 1 uses intuition, and results in quick decisions, which can be subject to error; System 2 is more deliberative, calculative, and less likely to produce errors. System 1 is based on heuristics, whereby a person develops shortcut approaches to making decisions. While heuristics can provide insight into a problem, careful deliberation should result in an

improved assessment. This implies that the elicitation of a prior distribution requires an analyst to engage the expert in System-2 thinking. Hammond (see [13]) describes a person's thinking as a continuum between the aforementioned dichotomy.

Tversky and Kahneman [14] were the first authors to make substantial contributions to the identification of heuristics used within probability assessments and to discuss the implications for bias. Three key heuristics – availability, representative, anchoring – are typically used when assessing probabilities.

The *availability heuristic* refers to a person's judgment being influenced by how easily historical events are recalled. As an example, an expert may believe the likelihood of a particular system failing is high because there was a recent failure event. This can lead to a biased assessment as the expert is not considering a full failure history of the system.

The *representative heuristic* refers to the similarity between an outcome and a population. For example, on assessing the probability that a new component design will have a mean lifetime in excess of 1000 operating hours, one may consider how well the existing component population represents the design being evaluated. Care is required in using such a heuristic because an expert may assign an intuitive measure of similarity rather than considering how the probability will change with respect to that of the existing population.

The *anchoring and adjusting heuristic* refers to the situation when an expert provides an initial assessment and all future assessments are derived from an adjustment of the initial assessment. For example, consider the situation where a prior distribution for the mean time to failure for a component is required from an expert. An initial assessment may correspond to a best guess, from which the expert may anchor upon the initial assessment to adjust for upper and lower bounds from which the distribution is determined. Research shows that the adjustments made are typically insufficient [4, 15].

Assessing Prior Distributions

If an expert provides subjective probabilities that are coherent, then these are not incorrect insofar as they reflect the beliefs of the expert. However, it is clear that different experts give different assessments, and so this raises the question of how one might assess

the “quality” or “usefulness” of such distributions. As Cooke [5] pointed out, there is no absolute measure of the correctness of a subjective assessment. However two measures are often used either quantitatively or qualitatively: calibration and information.

To assess the degree to which an expert’s assessments are well calibrated requires the subjective probabilities to be compared with a collection of observed realizations. For example, two experts could assess the same event with one expert providing a probability of 0.9 and the other a probability of 0.2. This event will either be realized or not. Since neither expert assigned a probability of 1 or 0, regardless of the outcome neither will be incorrect. The first expert would be calibrated if 90% of all events assessed by that expert at the 90% level are realized and 10% are not. While for the second expert, 20% of all events assessed by that expert at the 20% level are realized and 80% are not. For this example, both experts could be perfectly calibrated but provide very different probabilities.

Direct assessment of calibration is only possible if we are able to make observations directly on the quantity of interest. In many cases, for example the uncertainty of a failure rate, this is not the case and so the distribution of any directly observable quantities (such as the number of units failing up to a given time) would be a predictive distribution obtained as a mixture of the sampling distribution weighted by the prior. Hence calibration measurements would naturally confound the sampling distribution and the prior.

A second consideration for the usefulness of an expert’s prior distribution is information, which can be assessed through **mean squared error** between the observed realizations and the subjective probabilities, information scores, or a similar such formula. Stronger conclusions can be drawn from an informative prior distribution than from an uninformative one. It is ideal to have an informative, well-calibrated expert. Note that it is possible to have an uninformative, calibrated expert. For example, if upon assessing a mean time to failure an expert provides the entire range of positive real numbers below the median 50% of the time and above the median 50% of the time, then the expert is calibrated but not informative.

Improving Probability Assessors

The quality of subjective probabilities from an expert

is dependent upon both the expert’s experience and the method of elicitation. If the expert lacks experience, the prior distribution will be uninformative or misleading, regardless of the elicitation approach employed. Poorly designed elicitation techniques may degrade the quality of the information provided by experts. Fischhoff [16] proposes four necessary conditions to support improved judgment skills:

1. abundant practice with a set of reasonably homogeneous tasks;
2. clear-cut criterion events for outcome feedback;
3. task-specific reinforcement;
4. explicit admission of the need for learning.

There is extensive evidence that these are often not achieved in practice [10, 17].

Standard techniques for eliciting prior distributions that reflect the uncertainty of the expert are reported in the literature. See, for example, Cooke [5] and Meyer and Booker [18]. The choice of technique depends upon the quantity of interest, the selection of which has been given little attention in the literature.

One important consideration when selecting the quantity of interest is feedback to the expert. This is considered crucial for calibrating the expert and should be event specific [10, 16, 17]. In other words, the feedback must be with respect to assigning probabilities to particular classes of relevant events and not only feedback on the ability of the expert to assign probabilities to any situation. To increase the effectiveness of feedback in terms of learning, conditions that influence the event should reoccur as often as possible [16, 19]. Therefore, the factors on which the measure is conditioned should be as few and as general as possible.

Generic Processes

A necessary first step toward developing a method for eliciting expert judgment is to start with a general approach that possesses the required key features for any elicitation process and to tailor it to the desired situation.

Phillips [20], Clemen and Reilly [21], and Garthwaite *et al.* [22], for example, all describe generic processes. Another generic process, first developed by the Stanford Research Institute (SRI)

4 Prior Distribution Elicitation

for eliciting expert judgment is discussed in Spetzler *et al.* [23], Ferrell [24], and Merkhofer [9]. The issues addressed within the SRI process are common considerations within the alternatives. There are seven stages to the SRI approach: motivate, structure, condition, encode, verify, aggregate, and discretize.

Motivating the expert can be achieved by explaining the elicitation process and how the results will be used. This phase can be used to enhance the comprehension of an expert regarding the process, encourage an expert to provide an accurate assessment of his/her understanding, and determine potential biases, such as motivational biases. These include expert bias where an expert becomes overconfident merely because he/she has been given the title “expert” and management bias where an expert provides goals as opposed to judgment. For example, an expert states the aspiration that there will be no faults within this system by time of manufacture, rather than an assessment of his beliefs.

Structuring involves defining the specific event being considered to ensure there is no ambiguity in the questions and to explore how an expert thinks about the quantity for which probability judgment is to be elicited. The aim is to manage cognitive bias by simplifying the complex task of assigning probabilities by disaggregating the quantity of interest into more elementary variables [25]. However, the unpacking principle [13] may be the consequence. This refers to the situation where the more detailed the description of the event, the greater the likelihood assigned to it. For example, an expert may provide an assessment for the probability of a component failing and subsequently during the elicitation process provide probabilities associated with causes of failure that may result in a system probability exceeding the initial assessment.

Sometimes experts maybe unclear about whether they are being asked for conditional events or conjoined events ($P(A|B)$ or $P(A \text{ and } B)$), as these can be difficult to distinguish in natural language. Judgments can be conditioned upon all relevant information necessary to ensure that an expert’s awareness has been stimulated and to manage biases such as anchoring and availability.

Encoding refers to an expert providing a numerical expression that reflects his/her uncertainty regarding an outcome. There are a number of techniques available for encoding subjective probabilities. Common approaches range from direct **estimation** whereby a

person is simply asked for the probability to inferring probabilities from elicited preferences with specified lotteries. A few devices have been used to support such elicitation, such as probability wheels or visual analog scales. An interesting discussion of alternative methods is given by O’Hagan *et al.* [13].

Encoding a probability distribution is more challenging because additional information is required than for an individual probability. One could partition the distribution into discrete intervals and elicit probabilities for the value of interest belonging to each of the intervals. Evidence exists to suggest that people are better at estimating the median and mode rather than the mean; moreover people are poor at assessing or interpreting the variance [13].

A popular alternative encoding procedure for distributions is the fractile method [5], in which the expert assesses the median value of his/her subjective probability distribution along with the (25th, 75th) and the (5th, 95th) **percentiles**. Once these values have been elicited, a parametric distribution can be sought to maximize fit. The main drawback of this technique is that the elicited data often reflect a central bias [26]. However, after percentiles of the prior distribution have been assessed, graphical techniques can be applied to enhance the quality of the prior distribution [27].

Verification is required to ensure that an expert has provided a reflection of his/her true beliefs. If problems are encountered then the previous stages are to be repeated.

If multiple experts are assessing the same quantity of interest, then their individual probability distributions should be aggregated. There are two approaches to aggregation – mathematical and behavioral. The former implies the experts should not influence each others’ decisions [24]. The latter requires experts to share their judgment and reassess their distributions and includes techniques such as Delphi [24] and nominal group technique [28]. There are several mathematical approaches to aggregation, most of which aim to evaluate a weighted average across the experts. See Cooke [5] for a fuller discussion.

It is often necessary to treat continuous random variables as discrete during the encoding stage. *Discretizing* refers to techniques for fitting continuous distributions to the elicited data while preserving important **moments**. This is accomplished by

dividing the range of all possible values for the uncertain variable into intervals, selecting a representative point from each interval, and assigning that point the probability that the actual value will fall within the corresponding interval. The moments can be preserved through Gaussian quadrature techniques [29].

Two elicitation processes specific to reliability include PREDICT (Kerscher [30, 31] and REMM [32–34]). Both provide modeling frameworks designed to estimate reliability throughout system development beginning with a problem structuring phase, which consists of eliciting a graphical representation of the relationship between the potential failure modes and the system reliability. The graphs form the basis for the elicitation.

Summary and Conclusions

An overview of the key issues associated with the elicitation of a prior distribution has been presented; in particular, the shortcomings due to the prevalence of heuristics employed by an expert when assessing probabilities have been highlighted. Evidence indicates that an expert can improve his/her assessments given feedback about meaningful quantities of interest and this learning can be accelerated under the right conditions. Moreover, good subjective probability assessment requires a supportive process for the experts, whereby key stages are sequenced for managing specific biases. For further details about these issues see O'Hagan *et al.* [13], Meyer and Booker [18], and Cooke [5].

Practically, the design and implementation of an elicitation process requires considered **project management** to ensure that, for example, the correct experts are selected, the choice of elicitation method is relevant to the model requirements and parameterization, the integrity of the probabilities assessed are maintained, and that sufficient resources are obtained to support an effective, and efficient, process. See Meyer and Booker [18] for further discussion.

Theoretically, there is a need to infer from the assessments which probability distributions on model parameters are consistent. This approach has been developed by Cooke [35] with more algorithms and underlying theory for probabilistic inversion in Kraan and Bedford [36]. Taking a more standard Bayesian perspective, Percy [37] discusses the

indirect assessment of parameters from generic prior distributions through the direct assessment of quantiles of the predictive distribution which will have observable outcomes. Gutierrez-Pulido *et al.* [38] take a similar line, considering both moments and quantiles of the time to failure for a system as sources of information from which prior distributions can be fitted. Such methods could also be applicable to other Bayesian contexts where prior distributions on lifetime distribution parameters are to be assessed – for example in **Bayesian accelerated** or proportional hazards life modeling [39].

Elicitation of a prior distribution places a heavy cognitive burden on the subjective probability assessments by an expert. Yet observed data can exist for earlier generations of a system, component or process, although it is not clear how these data can be adapted to inform the assessment of a new design. **Empirical Bayes** provides a framework for integrating relevant historical data and hence can reduce the cognitive burden on an expert. See for example Quigley *et al.* [40] and Bedford *et al.* [41].

Masked Failure Data: Bayesian Modeling

Introduction

Suppose we have a system with J components and a defect in any component causes the system to fail. We test many of these identical systems to assess each component's reliability. In the ideal situation, the exact cause of the system's failure can be identified. Then a detailed **Failure Mode Effect Analysis** can be carried out. However, one often encounters the situation where the exact component causing the system to fail is unknown, nevertheless, it can be narrowed to a subset of components. So we have masked data that is, the data consist of the lifetimes of n systems randomly chosen for life testing and their associated labels identifying the probable components that may cause each system to fail. Masking is usually due to limited resources for diagnosing the causes of failures. More importantly, it is due to the modular nature of present systems. For example, in computer repair shops, the cause of failure is often isolated to a module of several components. The system is brought back into operation by replacing the whole module. The objective in analyzing the masked system **failure data** is to make inferences for the reliability of the components. The **system reliability** is usually derived from the **component reliability** and the system's configuration. Another objective is to make inference for the diagnostic probability that is, the probability of a specific component causing the system to fail given the set of probable causes and the system's failure time.

Recently, several authors studied this problem for the series system using exponential distributions for the component lifetimes. Most authors make an equiprobable assumption for the masking probabilities, where the conditional masking probabilities given each cause of failure in the masked set take the same value. This assumption (called the symmetry assumption by some authors) allows one to consider only the reduced likelihood. The work includes Miyakawa [1], Usher and Hodgson [2], Guess *et al.* [3], Lin *et al.* [4, 5], Doganaksoy [6], Gastaldi [7], Reiser *et al.* [8], Usher [9], Mukhopadhyay and Basu [10], Basu *et al.* [11] and a review article by Sen *et al.* [12].

To relax the equiprobable assumption, Lin and Guess [13], and Guttman *et al.* [14] consider a proportional probability model for a dependent masking probability for a two-component series system. They assume that the masking probability conditional on the first component's failure and the system's failure time is proportional to that of the second component. Although both masking probabilities are functions of the system's failure time, they assume the proportionality is independent of the system's failure time. Craiu and Duchesne [15] propose EM algorithms for models that allow the masking probabilities to depend on time. Craiu and Reiser [16] propose EM based approach for inference for dependent **competing risks** models.

In a similar spirit to relax the equiprobable assumption, Kuo and Yang [17] explore other probability assumptions for the masking probabilities. They explore two different stochastic models for the masking probabilities. One model allows the masking probabilities to have different values depending on the true cause of failure, but they do not depend on the system's failure time. The other model assumes the masking probabilities are further dependent on some monotone functions of the system's failure time. In addition to exponential distributions for the components, they also consider Weibull distributions. To ensure identifiability, they assume the components have independent failure distributions. They show that better predictive power can be achieved by modeling the masking probabilities without the equiprobable assumption. They demonstrate this with a simulated data set and with a real data set based on Dinse [18].

Note that the system's failure occurs at the earliest onset of any component's failure. So we are using the competing risk methodology in our analysis. Furthermore, we are assuming the components are acting independently for identifiability issue. **Markov chain Monte Carlo** (MCMC) methods are typically used for the Bayesian inference for the problems posed here. In particular, an MCMC algorithm augmented with latent variables that simulate the true causes of failures will be used for Bayesian computation of the component reliability. In addition, an **EM algorithm** [19] for this problem will also be illustrated.

Model selection by a predictive approach as in Geisser and Eddy [20] can be developed naturally from the Bayesian framework. Kuo and Yang [17]

2 Masked Failure Data: Bayesian Modeling

provide more details on the model determination and show that improved model can be obtained by modeling the masking probabilities.

The sections titled “Full Likelihood” and “Reduced Likelihood” describe the basic models for the equiprobable assumption. The section titled “Relaxing the Equiprobable Assumption” discusses two variations of the basic models that model the masking probabilities. The MCMC algorithms with auxiliary latent variable augmentation are developed for these models. Some numerical results for a simulated data set are given in the section titled “Simulation Study” to illustrate the techniques. A brief discussion on the model determination is given in the section titled “Conclusion”.

Full Likelihood

In the full likelihood formulation, we not only consider the system lifetimes but also the labels that identify the possible failed components. Let t_{ij} denote the random lifetime of the j th component in the i th system. Assume we observe a sample of n **series systems** each having J components; therefore we observe $t_i = \min(t_{i1}, \dots, t_{iJ})$, for $i = 1, \dots, n$. In addition, for each system, we observe a set of labels of the components that include the failed component. Let S_i denote the set of components (labels) that possibly cause the system i to fail, and let s_i denote the realized set for S_i . The observed data denoted by $\mathbf{d}$ consist of $(t_1, s_1), \dots, (t_n, s_n)$. If each set s_i is a singleton, then this reduces to the usual competing risk study where the exact cause of failure is identified. The set of labels is often masked because the true cause of failure is hiding with other components. Let K_i denote the index of the component actually causing the i th system to fail. It is a singleton because of the series system and continuous lifetimes. Let f_j denote the density for the j th component's lifetime and $\bar{F}_j$ denote its survival function. We assume the component lifetime distributions are independent. For the i th system, the likelihood contribution coming from the datum (t_i, s_i) consists of $p(t_i, s_i)$. This can be written as $\sum_{j=1}^J p(t_i, K_i = j)p(s_i|t_i, K_i = j)$. Note the masking probability $p(s_i|t_i, K_i = j) = 0$, if $j \notin s_i$. Moreover, we have: $p(t_i, K_i = j) = f_j(t_i) \prod_{l=1, l \neq j}^J \bar{F}_l(t_i)$. Therefore the

full likelihood of this data set is

$$L_F = \prod_{i=1}^n \left[\sum_{j \in s_i} \left\{ \left(f_j(t_i) \prod_{l=1, l \neq j}^J \bar{F}_l(t_i) \right) \times P(S_i = s_i | T_i = t_i, K_i = j) \right\} \right] \quad (1)$$

It is often of interest to compute the diagnostic probability that is, the probability that the j th component actually causing the system to fail given the possible malfunctioning subset and the system's failure time. For the i th system and $j \in s_i$, the diagnostic probability for the j th cause is

$$\begin{aligned} p(k_i = j | s_i, t_i) &= \frac{p(k_i = j, s_i, t_i)}{p(s_i, t_i)} \\ &= \frac{P(S_i = s_i | T_i = t_i, K_i = j) f_j(t_i) \times \prod_{l=1, l \neq j}^J \bar{F}_l(t_i)}{\sum_{j \in s_i} P(S_i = s_i | T_i = t_i, K_i = j) \times f_j(t_i) \prod_{l=1, l \neq j}^J \bar{F}_l(t_i)} \end{aligned} \quad (2)$$

Reduced Likelihood

Several authors assume an equiprobable assumption where the masking probabilities take on the same value irrelevant of the particular cause of failure. That is, they make the following assumption for a fixed $j \in s_i$:

$$\begin{aligned} P(S_i = s_i | T_i = t_i, K_i = j') &= P(S_i = s_i | T_i = t_i, \\ &K_i = j) \text{ for all } j' \in s_i \end{aligned} \quad (3)$$

Then they proceed with their analysis with a reduced likelihood that does not depend on the masking probabilities:

$$L_R = \prod_{i=1}^n \left[\sum_{j \in s_i} \left\{ f_j(t_i) \prod_{l=1, l \neq j}^J \bar{F}_l(t_i) \right\} \right] \quad (4)$$

Reiser *et al.* [8] provide a Bayesian analysis with this reduced likelihood assuming exponential distributions $f_j(t_i) = \lambda_j e^{-\lambda_j t_i} I\{t_i > 0\}$, and the noninformative Jeffrey's prior:

$$\pi(\lambda_1, \dots, \lambda_J) \propto \prod_{j=1}^J \lambda_j^{-1} \quad (5)$$

For the system with $J = 2$, let n_1 , n_2 , and n_{12} denote the numbers of systems in the sample with true causes identified to be the first component, the second component, or masked (either component). Then we can summarize the observed data with $T = \sum_{i=1}^n t_i$ (**total time on test**), and n_1 , n_2 , and n_{12} . Then the posterior density of λ_1, λ_2 given the data is

$$\begin{aligned} \pi(\lambda_1, \lambda_2 | \mathbf{d}) &\propto \exp\{-T(\lambda_1 + \lambda_2)\} \lambda_1^{n_1-1} \lambda_2^{n_2-1} \\ &\times (\lambda_1 + \lambda_2)^{n_{12}} \end{aligned} \quad (6)$$

So they show the Bayes estimators (the posterior means) are given by

$$\tilde{\lambda}_1 = \frac{n_1}{T} \frac{n_1 + n_2 + n_{12}}{n_1 + n_2} \quad (7)$$

$$\tilde{\lambda}_2 = \frac{n_2}{T} \frac{n_1 + n_2 + n_{12}}{n_1 + n_2} \quad (8)$$

They are exactly the maximum likelihood estimators given by Usher and Hodgson [2]. An MCMC algorithm for computing the Bayes estimates can be developed easily that will be given in the subsection titled "Gibbs Sampling for the Reduced Model" as a special case of the algorithm. The MCMC algorithm allows us to compute **quantiles**, other functionals of the posterior distribution, and the highest posterior density credible sets.

Lin *et al.* [5] use a step-function prior to λ_j :

$$\pi(\lambda_j) = \sum_{k=1}^{\infty} \alpha_{j,k} I\{\lambda_j \in [a_{k-1}, a_k)\} \quad (9)$$

where I denotes the indicator function and $\sum_{k=1}^{\infty} \alpha_{j,k} (a_k - a_{k-1}) = 1$ satisfying the probability constraint. They provide a numerical example for the $J = 2$ system. An MCMC algorithm with data augmentation similar to Yang and Kuo [21] can be developed easily for this problem.

Relaxing the Equiprobable Assumption

Most of the Bayesian analysis is based on the equiprobable assumption for the masking probability. So reduced likelihood can be used. There are some treatments on relaxing the equiprobable assumption. For example, Kuo and Yang [17] model the masking probabilities from the simple classification point of view. One of the simple assumptions is to make the probabilities independent of the time and having different values conditional on their components. Let us look at the two-components system. Assume $P(S_i = \{1\} | t_i, K_i = 1) = \theta_1$, and $P(S_i = \{2\} | t_i, K_i = 2) = \theta_2$. Consequently, $P(S_i = \{1, 2\} | t_i, K_i = 1) = 1 - \theta_1$, and $P(S_i = \{1, 2\} | t_i, K_i = 2) = 1 - \theta_2$. Then the full likelihood in this case is

$$\begin{aligned} L_F &= \prod_{i|s_i=\{1\}} \theta_1 f_1(t_i) \bar{F}_2(t_i) \prod_{i|s_i=\{2\}} \theta_2 f_2(t_i) \bar{F}_1(t_i) \\ &\times \prod_{i|s_i=\{1,2\}} \{(1 - \theta_1) f_1(t_i) \bar{F}_2(t_i) \\ &+ (1 - \theta_2) f_2(t_i) \bar{F}_1(t_i)\} \end{aligned} \quad (10)$$

Let us note the cardinalities of the indices in each product in equation (10) are exactly n_1 , n_2 , and n_{12} , defined earlier in the section titled "Reduced Likelihood".

The same idea can be generalized to an arbitrary number of components. For example for $J = 3$, we define the following masking probabilities: $P(S_i = \{j\} | t_i, K_i = j) = \theta_j$ for all j , $P(S_i = \{1, 2\} | t_i, K_i = 1) = \theta_{12|1}$, and $P(S_i = \{1, 3\} | t_i, K_i = 1) = \theta_{13|1}$. Consequently, $P(S_i = \{1, 2, 3\} | t_i, K_i = 1) = 1 - \theta_1 - \theta_{12|1} - \theta_{13|1}$. Similarly for causes two and three. These statements can be simplified if we know more about the configuration of the system. For example, components one and two are mounted on the same card separately from component three. Then we can assume $\theta_{13|1} = \theta_{23|2} = \theta_{13|3} = \theta_{23|3} = 0$. There will be fewer parameters to be estimated. Aboul-Séoud and Usher [22] describe an example of the modular system structure.

If the replaced modules are further sent to the factories for identifying the exact component causing the failure, we can produce fairly accurate estimates of the θ 's from the follow-up study. Therefore, we can estimate f_j by assuming the θ 's are known. Alternatively, we can combine the original data

4 Masked Failure Data: Bayesian Modeling

$(t_i, s_i), i = 1, \dots, n$, with the follow-up “autopsy” data to obtain better inferences as done in Flehinger *et al.* [23, 24], and Reiser *et al.* [25].

In addition to exponential distributions for the component lifetimes, we will also consider Weibull distributions for F_j . Gibbs sampling will be developed for Bayesian inference for the θ ’s and the parameters in f_j . Although we concentrate on the two-components system here for illustration, the Gibbs sampler can be extended straightforwardly to any number of components. The method is akin to the Gibbs sampling used in many aggregated models (cf. [21]).

Gibbs Sampling for the Full Model

Let us define the hazard function $h_j(t) = f_j(t)/\bar{F}_j(t)$ for all j . Then equation (10) can be rewritten as

$$L_F = \left(\prod_{i|s_i=\{1\}} \theta_1 h_1(t_i) \prod_{i|s_i=\{2\}} \theta_2 h_2(t_i) \right. \\ \left. \times \prod_{i|s_i=\{1,2\}} \{(1 - \theta_1)h_1(t_i) + (1 - \theta_2)h_2(t_i)\} \right) \\ \times \left(\prod_{i=1}^n \bar{F}_1(t_i) \bar{F}_2(t_i) \right) \quad (11)$$

The summation in the third product of this likelihood prevents us from updating the parameters in F easily. Therefore, we introduce latent variables z_i for the systems where the cause of failure is masked. Let z_i be a Bernoulli variable with the success ($z_i = 1$) probability to be $p_i = (1 - \theta_1)h_1(t_i)/\{(1 - \theta_1)h_1(t_i) + (1 - \theta_2)h_2(t_i)\}$ for i with $s_i = \{1, 2\}$. It is interesting to note that this probability of success p_i is exactly the diagnostic probability $p(k_i = 1|s_i, t_i)$ in equation (2) for the true cause due to the first component conditional on $s_i = \{1, 2\}$ and t_i being observed. Let $z_+ = \sum_{i|s_i=\{1,2\}} z_i$. Then the conditional density of $\theta = (\theta_1, \theta_2)$ and the unknown parameters λ in F ’s given $\mathbf{d}$ and the latent variables $\mathbf{z}$ is

$$f(\theta, \lambda | \mathbf{z}, \mathbf{d}) \propto \theta_1^{n_1} (1 - \theta_1)^{z_+} \theta_2^{n_2} (1 - \theta_2)^{n_{12} - z_+} \\ \times \left(\prod_{i|s_i=\{1\}} h_1(t_i) \prod_{i|s_i=\{2\}} h_2(t_i) \right)$$

$$\times \prod_{i|s_i=\{1,2\}} h_1(t_i)^{z_i} h_2(t_i)^{1-z_i} \\ \times \left(\prod_{i=1}^n \bar{F}_1(t_i) \bar{F}_2(t_i) \right) \pi(\theta, \lambda) \quad (12)$$

where π denotes the prior density of θ and λ . Therefore, updating θ and λ can be done easily and independently for independent prior on θ and λ . We are assuming that readers are familiar with the basics of MCMC algorithms as described in Gelfand and Smith [26] and Tanner and Wong [27]. In the following, we only describe the transitional kernel in the MCMC algorithm. Now we write the Gibbs steps for two special cases, one for each component to have an exponential distribution and the other to have a Weibull distribution.

- (1) The exponential component $\bar{F}_j(t) = \exp(-\lambda_j t)$:

We consider a prior with the following independent components for $j = 1$ and 2 : $\theta_j \sim \beta e(\alpha_j, \beta_j)$ and $\lambda_j \sim G(a_j, b_j)$, where $G(a_j, b_j)$ denotes a gamma density with mean a_j/b_j . The conjugate priors for θ_j and λ_j in the augmented likelihood are chosen so that we can easily specify the conditional densities in the Gibbs algorithm. Gamma and beta prior densities are also versatile enough to incorporate various shapes for the distributions of the unknown parameters.

Step a (data augmentation step): given θ and λ , we generate $z_i \sim B(1, (1 - \theta_1)\lambda_1 / \{(1 - \theta_1)\lambda_1 + (1 - \theta_2)\lambda_2\})$ a Bernoulli distribution, independently for each i with $s_i = \{1, 2\}$. Then we compute $z_+ = \sum_{i|s_i=\{1,2\}} z_i$.

Step b (parameter updating step): given $\mathbf{z}$ and $\mathbf{d}$, we update the parameters by:

$$\theta_1 | \mathbf{z}, \mathbf{d}, \theta_2, \\ \lambda \sim \text{Beta}(\alpha_1 + n_1, \beta_1 + z_+) \quad (13)$$

$$\theta_2 | \mathbf{z}, \mathbf{d}, \theta_1, \\ \lambda \sim \text{Beta}(\alpha_2 + n_2, \beta_2 + n_{12} - z_+) \quad (14)$$

$$\lambda_1 | \mathbf{z}, \mathbf{d}, \lambda_2, \\ \theta \sim G\left(a_1 + n_1 + z_+, b_1 + \sum_{i=1}^n t_i\right) \quad (15)$$

$$\lambda_2|\mathbf{z}, \mathbf{d}, \lambda_1, \boldsymbol{\theta} \sim G \times \left(a_2 + n_2 + n_{12} - z_+, \quad b_2 + \sum_{i=1}^n t_i \right) \quad (16)$$

Note that the parameters $\theta_1, \theta_2, \lambda_1$ and λ_2 are conditionally independent given $\mathbf{z}$, and $\mathbf{d}$ from the above expressions. Therefore, updating the four parameters can be done in parallel.

(2) The Weibull component $\bar{F}_j(t) = \exp(-\lambda_j t^{\rho_j})$:

We consider a prior with the following independent components: $\theta_j \sim \text{Beta}(\alpha_j, \beta_j)$, $\lambda_j \sim G(a_j, b_j)$, and ρ_j has density $\pi(\rho_j)$ that can be arbitrary. The same ideas can be generalized to a system with more than two components. The assumption of independent components in the prior is chosen for convenience. We have chosen the gamma distribution for λ_j for conjugacy. We can choose the prior on ρ_j to be uniformly distributed over $(0, m_j)$ as suggested by Sinha [28, p.160]. We can also explore the choice $\pi(\rho_j, \lambda_j) \propto 1/(\rho_j \lambda_j)$ as given by Sinha and Zellner [29]. Let $\boldsymbol{\rho} = (\rho_1, \rho_2)$.

Step a (data augmentation step): given $\boldsymbol{\theta}, \boldsymbol{\lambda}$ and $\boldsymbol{\rho}$, we generate $z_i \sim B(1, (1 - \theta_1)\lambda_1\rho_1 t_i^{\rho_1-1} / \{(1 - \theta_1)\lambda_1\rho_1 t_i^{\rho_1-1} + (1 - \theta_2)\lambda_2\rho_2 t_i^{\rho_2-1}\})$, independently for i with $s_i = \{1, 2\}$. Then we compute $z_+ = \sum_{i|s_i=\{1,2\}} z_i$.

Step b (parameter updating step): given $\mathbf{z}$ and $\mathbf{d}$, we update the parameters by:

$$\theta_1|\mathbf{z}, \mathbf{d}, \boldsymbol{\lambda}, \boldsymbol{\rho}, \theta_2 \sim \text{Beta}(\alpha_1 + n_1, \beta_1 + z_+) \quad (17)$$

$$\theta_2|\mathbf{z}, \mathbf{d}, \boldsymbol{\lambda}, \boldsymbol{\rho}, \theta_1 \sim \text{Beta}(\alpha_2 + n_2, \beta_2 + n_{12} - z_+) \quad (18)$$

$$\lambda_1|\mathbf{z}, \mathbf{d}, \boldsymbol{\rho}, \boldsymbol{\theta}, \lambda_2 \sim G\left(a_1 + n_1 + z_+, \quad b_1 + \sum_{i=1}^n t_i^{\rho_1}\right) \quad (19)$$

$$\lambda_2|\mathbf{z}, \mathbf{d}, \boldsymbol{\rho}, \boldsymbol{\theta}, \lambda_1 \sim G\left(a_2 + n_2 + n_{12} - z_+, \quad b_2 + \sum_{i=1}^n t_i^{\rho_2}\right) \quad (20)$$

and update the parameters ρ_1 and ρ_2 independently given $\mathbf{z}, \mathbf{d}, \boldsymbol{\lambda}$ and $\boldsymbol{\theta}$, each by the Metropolis law (cf.

[30], and [31, 32]) with the following density as the target density:

$$\begin{aligned} \pi(\rho_1|\mathbf{z}, \mathbf{d}, \boldsymbol{\lambda}, \boldsymbol{\theta}) &\propto \rho_1^{n_1+z_+} \left(\prod_{i|s_i=\{1\}} t_i^{\rho_1-1} \right) \\ &\times \left(\prod_{i|s_i=\{1,2\}} t_i^{(\rho_1-1)z_i} \right) \exp \\ &\times \left(-\lambda_1 \sum_{i=1}^n t_i^{\rho_1} \right) \pi(\rho_1) \end{aligned} \quad (21)$$

$$\begin{aligned} \pi(\rho_2|\mathbf{z}, \mathbf{d}, \boldsymbol{\lambda}, \boldsymbol{\theta}) &\propto \rho_2^{n_2+n_{12}-z_+} \left(\prod_{i|s_i=\{2\}} t_i^{\rho_2-1} \right) \\ &\times \left(\prod_{i|s_i=\{1,2\}} t_i^{(\rho_2-1)(1-z_i)} \right) \\ &\times \exp(-\lambda_2 \sum_{i=1}^n t_i^{\rho_2}) \pi(\rho_2) \end{aligned} \quad (22)$$

Note in the above updating, the generation of $\boldsymbol{\theta}$ and $(\boldsymbol{\lambda}, \boldsymbol{\rho})$ can be done independently.

To generalize the above discussion to three components, we can easily extend the same prior for $\boldsymbol{\lambda}, \boldsymbol{\rho}$ in the component lifetimes to more components. For the masking probabilities $\boldsymbol{\theta}_1 = (\theta_1, \theta_{12|1}, \theta_{13|1}, \theta_{123|1})$ with $\theta_1 + \theta_{12|1} + \theta_{13|1} + \theta_{123|1} = 1$, a Dirichlet prior with parameters $(\alpha_1, \alpha_2, \alpha_3, \alpha_4)$ can be considered. Similarly, we can define independent Dirichlet priors for the other masking probabilities $\boldsymbol{\theta}_2$ and $\boldsymbol{\theta}_3$, where $j = 2$ or $j = 3$ is the true cause of failure. Then we can employ the same data augmentation idea as before and updating the parameters $\boldsymbol{\theta}_1, \boldsymbol{\theta}_2$, and $\boldsymbol{\theta}_3$ independently, each with an updated Dirichlet distribution.

EM Algorithm for the Full Model

If we are only interested in the posterior mode or the mode of the likelihood with their error estimates, we can apply the EM algorithm [19]. The algorithm may be simpler than the Gibbs sampler in implementation, it also may converge faster. The EM algorithm essentially converts a complicated optimization problem to many simpler iterative steps. The iteration steps are similar to that in the Gibbs algorithm, except the data

6 Masked Failure Data: Bayesian Modeling

augmentation step is replaced by an E-step (expectation) where the missing data (latent variables) are replaced by their expectations, and the parameter updating step is replaced by a maximization step. In the following, we make the same prior assumption as in the previous subsection to obtain the posterior mode. The algorithm can be easily modified to obtain the maximum likelihood estimate using the flat prior.

(1) For the exponential component, we make the following changes in the $l + 1st$ iteration:

Step a:

$$z_+^l = \frac{n_{12}(1 - \theta_1^l)\lambda_1^l}{(1 - \theta_1^l)\lambda_1^l + (1 - \theta_2^l)\lambda_2^l} \quad (23)$$

Step b:

$$\theta_1^{l+1} = \frac{\alpha_1 + n_1 - 1}{\alpha_1 + \beta_1 + n_1 + z_+^l - 2} \quad (24)$$

$$\theta_2^{l+1} = \frac{\alpha_2 + n_2 - 1}{\alpha_2 + \beta_2 + n_2 + n_{12} - z_+^l - 2} \quad (25)$$

$$\lambda_1^{l+1} = \frac{a_1 + n_1 + z_+^l - 1}{b_1 + \sum_{i=1}^n t_i} \quad (26)$$

$$\lambda_2^{l+1} = \frac{a_2 + n_2 + n_{12} - z_+^l - 1}{b_2 + \sum_{i=1}^n t_i} \quad (27)$$

(2) For the Weibull component:

Step a: the generation of z_i is replaced by setting $z_+^l = n_{12}(1 - \theta_1^l)\lambda_1^l \rho_1^l t_i^{\rho_1^l - 1} / \{(1 - \theta_1^l)\lambda_1^l \rho_1^l t_i^{\rho_1^l - 1} + (1 - \theta_2^l)\lambda_2^l \rho_2^l t_i^{\rho_2^l - 1}\}$.

Step b: the generation of θ_1 , θ_2 , λ_1 , and λ_2 is replaced by

$$\theta_1^{l+1} = \frac{\alpha_1 + n_1 - 1}{\alpha_1 + \beta_1 + n_1 + z_+^l - 2} \quad (28)$$

$$\theta_2^{l+1} = \frac{\alpha_2 + n_2 - 1}{\alpha_2 + \beta_2 + n_2 + n_{12} - z_+^l - 2} \quad (29)$$

$$\lambda_1^{l+1} = \frac{a_1 + n_1 + z_+^l - 1}{b_1 + \sum_{i=1}^n t_i^{\rho_1}} \quad (30)$$

$$\lambda_2^{l+1} = \frac{a_2 + n_2 + n_{12} - z_+^l - 1}{b_2 + \sum_{i=1}^n t_i^{\rho_2}} \quad (31)$$

and the Metropolis algorithm for generating ρ_1 and ρ_2 is replaced by finding ρ_1 that maximizes equation (21) and finding ρ_2 that maximizes equation (22).

Gibbs Sampling for the Reduced Model

Now we write the Gibbs sampler for the reduced model with the equiprobable assumption. Observe $1 - \theta_1 = 1 - \theta_2 = 1 - \theta$ in this case. We assume the same prior as the one in the full model except θ is $\beta e(\alpha_1, \beta_1)$ independent of other parameters. So the likelihood in this situation reduces to

$$L_R = \theta^{n_1+n_2} (1-\theta)^{n_{12}} \left(\prod_{i=1}^n \bar{F}_1(t_i) \bar{F}_2(t_i) \right) \prod_{i|s_i=\{1\}} h_1(t_i) \times \prod_{i|s_i=\{2\}} h_2(t_i) \prod_{i|s_i=\{1,2\}} \{h_1(t_i) + h_2(t_i)\} \quad (32)$$

So the Gibbs sampling for the exponential model is similar to the full model except z_i is generated by $B(1, \lambda_1/\{\lambda_1 + \lambda_2\})$, and instead of θ_1 and θ_2 , we generate a single $\theta \sim \beta e(\alpha_1 + n_1 + n_2, \beta_1 + n_{12})$. The Gibbs sampling for the Weibull model is the same as the full model except $\theta_1 = \theta_2 = \theta$ and we generate $\theta \sim \beta e(\alpha_1 + n_1 + n_2, \beta_1 + n_{12})$ to replace the generation of θ_1 and θ_2 .

Note the Gibbs sampler for the posterior distribution in equation (6) can be developed similarly. That is, we generate $z \sim \text{Bin}(n_{12}, \lambda_1/\{\lambda_1 + \lambda_2\})$ a binomial distribution, then generate $\lambda_1 \sim G(n_1 + z - 1, T)$, $\lambda_2 \sim G(n_2 + n_{12} - z - 1, T)$ independently.

EM Algorithm for the Reduced Model

The maximization for θ and other parameters can be done separately, where $\hat{\theta} = (\alpha_1 + n_1 + n_2 - 1)/(\alpha_1 + \beta_1 + n_1 + n_2 + n_{12} - 2)$ with no iteration. For other parameters we follow the same procedure as the EM algorithm for the full model in the subsection titled ‘‘EM Algorithm for the Full Model’’ with $\theta_1 = \theta_2$.

Simulation Study

We consider a series system with two exponential components, where $f_j(t) = \lambda_j \exp(-\lambda_j t)$, $j = 1, 2$, and $\lambda_1 = 0.01$ and $\lambda_2 = 0.005$. For each system, we

Table 1 Simulated data

Set of labels	System's failure time
$s_i = \{1\}$	3.4, 10.9, 71.5, 56.9, 41.6, 41.6, 38.6, 4.6, 8.5, 27.8, 2.9, 13.3, 37.4, 57.5, 168.1, 123.9, 136.3, 6.5, 21.4, 135.4, 93.1, 14.3, 10.8, 26.1, 95.3, 68.7, 22.3, 13.3, 73.4, 35.2, 28.0, 21.1
$s_i = \{2\}$	2.5, 212.2, 147.3, 63.6, 45.6, 4.2, 123.1, 10.5, 2.6, 27.4
$s_i = \{1, 2\}$	68.6, 2.3, 5.4, 8.8, 63.7, 325.2, 216.4, 132.0

simulate a pair of failure times from f_1 and f_2 respectively. Then, we take the minimum of the two failure times as the system's life time and note its label, the cause of the system's failure. If the cause is from the first (second) component, we randomly mask 10% (20%) of the observations. That is, the unmasked probabilities are $\theta_1 = 0.9$ and $\theta_2 = 0.8$. The data in Table 1 represent the failure time and cause of failure for a random sample of $n = 50$ systems.

We apply our analysis in the section titled "Relaxing the Equiprobable Assumption" to this simulated data set. We fit the data with the full model in equation (10) and the reduced model in equation (32) with exponentially distributed component lifetimes. Table 2 summarizes the priors, the posterior means, the EM estimates, and the posterior estimates of the diagnostic probability of the cause one for each of the full and reduced models. We choose uniform priors for the unmasked probabilities. We monitor the convergence of the Gibbs sampler using the Gelman and Rubin [33] method that uses the analysis of variance technique to determine whether or not further iterations are needed. We found 3 000 iterations

to be large enough for the priors being considered. All the following numerical results are obtained with 3 000 iterations and 50 replications in the Gibbs sampler. The table shows that the posterior means using the MCMC algorithm and the EM estimates are comparable. Starting at $\theta_1^0 = 0.5$, $\theta_2^0 = 0.5$, $\lambda_1^0 = 0.005$, $\lambda_2^0 = 0.005$, the EM algorithm converges after the 6th iteration when all the iteration error bounds are met, where each error bound for each parameter is set at the E^{-8} level. The diagnostic probability of the first cause conditional on $s_i = \{1, 2\}$ and t_i for such i is: $p(k_i = 1|t_i, s_i = \{1, 2\}) = (1 - \theta_1)\lambda_1 / \{(1 - \theta_1)\lambda_1 + (1 - \theta_2)\lambda_2\}$ for the full exponential model and $p(k_i = 1|t_i, s_i = \{1, 2\}) = \lambda_1 / (\lambda_1 + \lambda_2)$ for the reduced exponential model. Note these diagnostic probabilities are the same independent of t_i as long as i is such that $s_i = \{1, 2\}$. Table 2 also lists the posterior means for these two probabilities evaluated from the Gibbs sampler.

Conclusion

So far, we have presented several models for the masked system life times: full model and reduced model, each with exponential and Weibull component lifetimes. Which model is most desirable? We will use a predictive approach based on cross-validated data to address the model selection issue here. We can define the conditional predictive ordinate (CPO) for the i th data point for a model to be the predictive density evaluated at the i th data point given the remaining data. Then we define the pseudo-marginal predictive likelihood [20] to be the product of the CPOs over i . The pseudo-Bayes factor criterion is to select the model with the largest pseudo-marginal predictive likelihood. The computation of the CPOs

Table 2 Priors, posterior means, and Bayesian diagnostic probability estimates

Model	Full exponential	Reduced exponential
Prior	$\theta_i \sim \text{Beta}(1, 1)$ for $i = 1, 2$ $\lambda_i \sim G(1, 0.001)$ for $i = 1, 2$	$\theta \sim \text{Beta}(1, 1)$ $\lambda_i \sim G(1, 0.001)$ for $i = 1, 2$
Posterior means	$\hat{\theta}_1 = 0.866$, $\hat{\theta}_2 = 0.718$	$\hat{\theta} = 0.827$
Using Gibbs	$\hat{\lambda}_1 = 0.0125$, $\hat{\lambda}_2 = 0.0050$	$\hat{\lambda}_1 = 0.0131$, $\hat{\lambda}_2 = 0.0044$
Estimates	$\hat{\theta}_1 = 0.889$, $\hat{\theta}_2 = 0.714$	$\hat{\theta} = 0.840$
Using EM	$\hat{\lambda}_1 = 0.0121$, $\hat{\lambda}_2 = 0.00471$	$\hat{\lambda}_1 = 0.0128$, $\hat{\lambda}_2 = 0.00401$
$\hat{p}(k_i = 1 t_i, s_i = \{1, 2\})$ for each i with $s_i = \{1, 2\}$	0.53	0.75

follows straightforwardly from the Gibbs samplers. Details of this model determination are given in Kuo and Yang [17].

Bayesian Networks

Introduction

Bayesian networks (BNs), also known as *belief networks* (or Bayes nets for short), belong to the family of probabilistic *graphical models* (GMs). These graphical structures are used to represent knowledge about an uncertain domain. In particular, each node in the graph represents a random variable, while the edges between the nodes represent probabilistic dependencies among the corresponding random variables. These conditional dependencies in the graph are often estimated by using known statistical and computational methods. Hence, BNs combine principles from graph theory, **probability theory**, computer science, and statistics.

GMs with *undirected edges* are generally called *Markov random fields* or *Markov networks*. These networks provide a simple definition of independence between any two distinct nodes based on the concept of a *Markov blanket*. Markov networks are popular in fields such as statistical physics and computer vision [1, 2].

BNs correspond to another GM structure known as a *directed acyclic graph* (DAG) that is popular in the statistics, the machine learning, and the artificial intelligence societies. BNs are both mathematically rigorous and intuitively understandable. They enable an effective representation and computation of the joint probability distribution (JPD) over a set of random variables [3].

The structure of a DAG is defined by two sets: the set of nodes (vertices) and the set of directed edges. The nodes represent random variables and are drawn as circles labeled by the variable names. The edges represent direct dependence among the variables and are drawn by arrows between nodes. In particular, an edge from node X_i to node X_j represents a statistical dependence between the corresponding variables. Thus, the arrow indicates that a value taken by variable X_j depends on the value taken by variable X_i , or roughly speaking that variable X_i “influences” X_j . Node X_i is then referred to as a *parent* of X_j and, similarly, X_j is referred to as the *child* of X_i . An extension of these genealogical terms is often used to define the sets of “descendants” – the set of nodes that can be reached on a direct path from the node, or “ancestor” nodes – the set

of nodes from which the node can be reached on a direct path [4]. The structure of the acyclic graph guarantees that there is no node that can be its own ancestor or its own descendent. Such a condition is of vital importance to the factorization of the joint probability of a collection of nodes as seen below. Note that although the arrows represent direct causal connection between the variables, the *reasoning process* can operate on BNs by propagating information in any direction [5].

A BN reflects a simple conditional independence statement. Namely that each variable is independent of its nondescendants in the graph given the state of its parents. This property is used to reduce, sometimes significantly, the number of parameters that are required to characterize the JPD of the variables. This reduction provides an efficient way to compute the posterior probabilities given the evidence [3, 6, 7].

In addition to the DAG structure, which is often considered as the “qualitative” part of the model, one needs to specify the “quantitative” parameters of the model. The parameters are described in a manner which is consistent with a Markovian property, where the conditional probability distribution (CPD) at each node depends only on its parents. For discrete random variables, this conditional probability is often represented by a table, listing the local probability that a child node takes on each of the feasible values – for each combination of values of its parents. The joint distribution of a collection of variables can be determined uniquely by these local conditional probability tables (CPTs).

Following the above discussion, a more formal definition of a BN can be given [7]. A Bayesian network B is an annotated acyclic graph that represents a JPD over a set of random variables $\mathbf{V}$. The network is defined by a pair $B = \langle G, \Theta \rangle$, where G is the DAG whose nodes $X_1, X_2, \dots, X_n$ represents random variables, and whose edges represent the direct dependencies between these variables. The graph G encodes independence assumptions, by which each variable X_i is independent of its nondescendants given its parents in G . The second component Θ denotes the set of parameters of the network. This set contains the parameter $\theta_{x_i|\pi_i} = P_B(x_i|\pi_i)$ for each realization x_i of X_i conditioned on π_i , the set of parents of X_i in G . Accordingly, B defines a unique JPD over $\mathbf{V}$, namely:

2 Bayesian Networks

$$P_B(X_1, X_2, \dots, X_n) = \prod_{i=1}^n P_B(X_i | \pi_i) = \prod_{i=1}^n \theta_{X_i | \pi_i} \quad (1)$$

For simplicity of representation we omit the subscript B henceforth. If X_i has no parents, its local probability distribution is said to be *unconditional*, otherwise it is *conditional*. If the variable represented by a node is *observed*, then the node is said to be an evidence node, otherwise the node is said to be hidden or latent.

Consider the following example that illustrates some of the characteristics of BNs. The example shown in Figure 1 has a similar structure to the classical “earthquake” example in Pearl [3]. It considers a person who might suffer from a back injury, an event represented by the variable *Back* (denoted by B). Such an injury can cause a backache, an event represented by the variable *Ache* (denoted by A). The back injury might result from a wrong sport activity, represented by the variable *Sport* (denoted by S) or from new uncomfortable chairs installed at the person’s office, represented by the variable *Chair* (denoted by C). In the latter case, it is reasonable to assume that a coworker will suffer and report a similar backache syndrome, an event represented by the variable *Worker* (denoted by W). All variables are binary; thus, they are either true (denoted by “T”) or false (denoted by “F”).

The CPT of each node is listed besides the node.

In this example the parents of the variable *Back* are the nodes *Chair* and *Sport*. The child of *Back* is *Ache*, and the parent of *Worker* is *Chair*. Following the BN independence assumption, several independence statements can be observed in this case. For example, the variables *Chair* and *Sport* are marginally independent, but when *Back* is given they are conditionally dependent. This relation is often called *explaining away*. When *Chair* is given, *Worker* and *Back* are conditionally independent. When *Back* is given, *Ache* is conditionally independent of its ancestors *Chair* and *Sport*. The conditional independence statement of the BN provides a compact factorization of the JPDs. Instead of factorizing the joint distribution of all the variables by the chain rule, i.e., $P(C, S, W, B, A) = P(C)P(S|C)P(W|S, C)P(B|W, S, C)P(A|B, W, S, C)$, the BN defines a unique JPD in a factored form, i.e. $P(C, S, W, B, A) = P(C)P(S)P(W|C)P(B|S, C)P(A|B)$. Note that the BN form reduces the number of the model parameters, which belong to a multinomial distribution in this case, from $2^5 - 1 = 31$ to 10 parameters. Such a reduction provides great benefits from inference, learning (parameter **estimation**), and computational perspective. The resulting model is more robust with respect to **bias**-variance effects [8]. A practical graphical criterion that helps to

Figure 1 The backache BN example

investigate the structure of the JPD modeled by a BN is called *d-separation* [3, 9]. It captures both the conditional independence and dependence relations that are implied by the Markov condition on the random variables [2].

Inference via BN

Given a BN that specified the JPD in a factored form, one can evaluate all possible inference queries by marginalization, i.e. summing out over “irrelevant” variables. Two types of inference support are often considered: *predictive support* for node X_i , based on evidence nodes connected to X_i through its parent nodes (also called *top-down reasoning*), and *diagnostic support* for node X_i , based on evidence nodes connected to X_i through its children nodes (also called *bottom-up reasoning*). Given the example in Figure 1, one might consider the diagnostic support for the belief on new uncomfortable chairs installed at the person’s office, given the observation that the person suffers from a backache. Such a support is formulated as follows:

$$P(C = T|A = T) = \frac{P(C = T, A = T)}{P(A = T)} \quad (2)$$

where

$$\begin{aligned} P(C = T, A = T) = & \sum_{S, W, B \in \{T, F\}} P(C = T)P(S) \\ & \times P(W|C = T)P(B|S, C = T)P(A = T|B) \end{aligned} \quad (3)$$

and

$$\begin{aligned} P(A = T) = & \sum_{S, W, B, C \in \{T, F\}} P(C)P(S)P(W|C)P(B|S, C) \\ & \times P(A = T|B) \end{aligned} \quad (4)$$

Note that even for the binary case, the JPD has size $O(2^n)$, where n is the number of nodes. Hence, summing over the JPD takes exponential time. In general, the full summation (or integration) over discrete (continuous) variables is called *exact inference* and known to be an *NP-hard problem*. Some efficient algorithms exist to solve the exact inference problem in restricted classes of networks. One of the most popular algorithms is the *message passing algorithm* that solves the problem in $O(n)$ steps (linear in the number

of nodes) for *polytrees* (also called *singly connected networks*), where there is at most one path between any two nodes [3, 5]. The algorithm was extended to general networks by Lauritzen and Spiegelhalter [10]. Other exact inference methods include the *cycle-cutset* conditioning [3] and variable elimination [11].

Approximate inference methods were also proposed in the literature, such as *Monte Carlo* sampling that gives gradually improving estimates as sampling proceeds [9]. A variety of standard *Markov chain Monte Carlo* (MCMC) methods, including the *Gibbs sampling* and the *Metropolis–Hastings algorithm*, were used for approximate inference [4]. Other methods include the *loopy belief propagation* and *variational methods* [12] that exploit the **law of large numbers** to approximate large sums of random variables by their means.

BN Learning

In many practical settings the BN is unknown and one needs to learn it from the data. This problem is known as the *BN learning problem*, which can be stated informally as follows: Given training data and prior information (e.g., **expert knowledge**, **casual relationships**), estimate the graph topology (network structure) and the parameters of the JPD in the BN.

Learning the BN structure is considered a harder problem than learning the BN parameters. Moreover, another obstacle arises in situations of *partial observability* when nodes are hidden or when data is missing. In general, four BN learning cases are often considered, to which different learning methods are proposed, as seen in Table 1 [13].

In the first and simplest case the goal of learning is to find the values of the BN parameters (in each CPD) that maximize the (log)likelihood of the training

Table 1 Four cases of BN learning problems

Case	BN structure	Observability	Proposed learning method
1	Known	Full	Maximum-likelihood estimation
2	Known	Partial	EM (or gradient ascent), MCMC
3	Unknown	Full	Search through model space
4	Unknown	Partial	EM + search through model space

4 Bayesian Networks

dataset. This dataset contains m cases that are often assumed to be independent. Given training dataset $\Sigma = \{\mathbf{x}_1, \dots, \mathbf{x}_m\}$, where $\mathbf{x}_l = (x_{l1}, \dots, x_{ln})^T$, and the parameter set $\Theta = (\theta_1, \dots, \theta_n)$, where θ_i is the vector of parameters for the conditional distribution of variable X_i (represented by one node in the graph), the log-likelihood of the training dataset is a sum of terms, one for each node:

$$\log L(\Theta|\Sigma) = \sum_m \sum_n \log P(x_{li}|\pi_i, \theta_i) \quad (5)$$

The log-likelihood scoring function *decomposes* according to the graph structure; hence, one can maximize the contribution to the log-likelihood of each node independently [14]. Another alternative is to assign a prior **probability density function** to each parameter vector and use the training data to compute the posterior parameter distribution and the Bayes estimates. To compensate for zero occurrences of some sequences in the training dataset, one can use appropriate (mixtures of) conjugate prior distributions, e.g. the Dirichlet prior for the multinomial case as in the above backache example or the Wishart prior for the Gaussian case. Such an approach results in a maximum *a posteriori* estimate and is also known as the *equivalent sample size* (ESS) method.

In general, the other learning cases are computationally intractable. In the second case with known structure and partial observability, one can use the **EM (expectation maximization) algorithm** to find a locally optimal maximum-likelihood estimate of the parameters [4]. MCMC is an alternative approach that has been used to estimate the parameters of the BN model. In the third case, the goal is to learn a DAG that best explains the data. This is an NP-hard problem, since the number of DAGs on N variables is superexponential in N . One approach is to proceed with the simplest assumption that the variables are conditionally independent given a class, which is represented by a single common parent node to all the variable nodes. This structure corresponds to the *naïve BN*, which surprisingly is found to provide reasonably good results in some practical problems. To compute the Bayesian score in the fourth case with partial observability and unknown graph structure, one has to marginalize out the hidden nodes as well as the parameters. Since this is usually intractable, it is common to use an asymptotic approximation to the posterior called *Bayesian information criterion* (BIC) also known as the *minimum description*

length (MDL) approach. In this case one considers the trade-off effects between the likelihood term and a penalty term associated with the model complexity. An alternative approach is to conduct local search steps inside of the M step of the EM algorithm, known as *structural EM*, that presumably converges to a local maximum of the BIC score [7, 13].

BN and Other Markovian Probabilistic Models

It is well known that classic machine learning methods like Hidden Markov models (HMMs), **neural networks**, and Kalman filters can be considered as special cases of BNs [4, 13]. Specific types of BN models were developed to address stochastic processes, known as *dynamic BN*, and counterfactual information, known as *functional BN* [5]. Ben-Gal *et al.* [8] defined a hierarchical structure of Markovian GMs, which we follow here. The structure is described within the framework of DNA sequence classification, but is relevant to other research areas. The authors introduce the *variable-order Bayesian network* (VOBN) model as an extension of the *position weight matrix* (PWM) model, the *fixed-order Markov model* (MM) including HMMs, the *variable-order Markov* (VOM) model, and the BN model.

The PWM model is presumably the simplest and the most common context-independent model for DNA sequence classification. The basic assumption of the PWM model is that the random variables (e.g., nucleotides at different positions of the sequence) are statistically independent. Since this model has no memory it can be regarded as a fixed-order MM of order 0. In contrast, higher fixed-order models, such as MMs, HMMs, and interpolated MMs, rely on the statistical dependencies within the data to indicate repeating motifs in the sequence.

VOM models stand in between the above two types of models with respect to the number of model parameters. In fact, VOM models do not ignore statistical dependencies between variables in the sequence, yet, they take into account only those dependencies that are statistically significant. In contrast to fixed-order MMs, where the order is the same for all positions and for all contexts, in VOM models the order may vary for each position, based on its contexts.

Unlike the VOM models, which are homogeneous and which allow statistical dependences only between

Figure 2 Hierarchical structure of Markovian graphical models [© OUP, 2005.]

adjacent variables in the sequence, VOBN models are inhomogeneous and allow statistical dependencies between nonadjacent positions in a manner similar to BN models. Yet, as opposed to BN models, where the order of the model at a given node depends only on the size of the set of its parents, in VOBN models the order also depends on the context, i.e. on the specific observed realization in each set of parents. As a result, the number of parameters that need to be estimated in VOBN models is potentially smaller than in BN models, yielding a smaller chance for overfitting of the VOBN model to the training dataset. Context-specific BNs (e.g., [15, 16]) are closely related to, yet constructed differently from, the VOBN models [8].

To summarize, the VOBN model can be regarded as an extension of PWM, fixed-order Markov, and BN models as well as VOM models in the sense that these four models are special cases of the VOBN model. This means that in cases where statistical dependencies are insignificant, the VOBN model degenerates to the PWM model. If statistical dependencies exist only between adjacent positions in the sequence and the memory length is identical for all contexts, the VOBN model degenerates to an inhomogeneous fixed-order MM. If, in addition, the CPDs are identical for all positions, the VOBN model degenerates to a homogeneous fixed-order MM. If the memory length for a given position is identical for all contexts and depends only on the number

of parents, the VOBN model degenerates to a BN model. If the context-dependent statistical dependencies in the VOBN model are restricted to adjacent positions, the VOBN model degenerates to the inhomogeneous VOM model. If, in addition, the context-dependent CPDs are identical for all positions, the VOBN model degenerates to a homogeneous VOM model. Figure 2 sketches these relationships between fixed-order MMs, BN models, VOM models, and VOBN models.

Summary

BNs became extremely popular models in the last decade. They have been used for applications in various areas, such as machine learning, text mining, natural language processing, speech recognition, signal processing, bioinformatics, error-control codes, medical diagnosis, weather forecasting, and cellular networks.

The name BNs might be misleading. Although the use of Bayesian statistics in conjunction with BN provides an efficient approach for avoiding data overfitting, the use of BN models does not necessarily imply a commitment to Bayesian statistics. In fact, practitioners often follow frequentists' methods to estimate the parameters of the BN. On the other hand, in a general form of the graph, the nodes can represent not only random variables but also

hypotheses, beliefs, and latent variables [13]. Such a structure is intuitively appealing and convenient for the representation of both causal and probabilistic semantics. As indicated by David [17], this structure is ideal for combining prior knowledge, which often comes in causal form, and observed data. BN can be used, even in the case of missing data, to learn the causal relationships and gain an understanding of the various problem domains and to predict future events.

Bayesian Control Charts

Introduction

Standard control charts proposed by Shewhart (*see Control Charts, Overview*) are based on inspecting a sample of size n at intervals of h time units and issuing an alarm if the result of the sample is k standard deviation worse than what would be expected if the process were in its desired or target state. Usually, k is assumed equal to 3. The alarm signals that the process is deemed to be in an out-of-control state, which is characterized by deteriorated performances. Bayesian approaches for process monitoring have the same main objective as the Shewhart scheme; however, they use Bayes' theorem to update the information on the process state. Among these approaches, two basic schemes can be distinguished. The first is based on the seminal work by Girshick and Rubin [1], who first showed that all the information on the process, accumulated from the beginning of the production run, can be summarized in the posterior probability that the process is out of control. According to this approach, an out-of-control signal should be issued depending on this posterior probability. The set of approaches relying on this assumption are presented in the section titled "Bayesian Control Charting Based on the Posterior Probability that the Process is Out of Control", where it is shown that these Bayes-type control charts result in dynamic or adaptive schemes, that is, control charts in which at least one of the parameters n , h , and k can vary depending on information coming out from the process (*see Variable Sampling Rate Control Charts*). Connections with cumulative sum (CUSUM) control charts and Shewhart control charts are further shown in this section.

A second type of Bayesian control scheme found the out-of-control rule on the posterior distribution of the parameter of interest (e.g., the process mean if the objective is to maintain control over the process level). The section titled "Bayesian Control Charting Based on the Posterior Distribution of Process Parameters" briefly reviews approaches which share this common framework, outlining the main differences among them.

Bayesian Control Charting Based on the Posterior Probability that the Process is Out of Control

Assume that the production process can be in two possible states and let S_t represent the state at time t . The first state ($S_t = 0$) is the desirable or target state, usually referred to as the "in-control state". The second state ($S_t = 1$) is the state in which the process has deteriorated performance (e.g., a higher number of nonconforming items is produced) and is hence referred to as the "out-of-control" state. The shift from the in-control to the out-of-control state is due to an **assignable cause**, which is assumed to occur according to a **Poisson process**. Given this assumption, the time of occurrence of the assignable cause is an exponentially distributed random variable with mean $1/\nu$.

Unfortunately, the state of the process cannot be directly observed. The observable quantity at time t is denoted by Y_t and is related to the state of the underlying or "core" process through the probability densities $f_0(y_t)$ and $f_1(y_t)$ by the following relationships:

$$Y_t|S_t \sim \begin{cases} f_0(y_t) & \text{for } S_t = 0 \\ & \text{(process is in control)} \\ f_1(y_t) & \text{for } S_t = 1 \\ & \text{(process is out of control)} \end{cases} \quad (1)$$

Assume that the observable quantity Y_t can be inspected each h time units, because of technical reasons. Therefore, without loss of generality, the time index t will denote the generic t th inspection time, that is, inspection will occur at time $h, 2h, \dots, th, \dots$.

The control procedure consists in observing the quantity Y_t at each inspection epoch in order to decide whether the state of the core process is 0 or 1. If the process is considered to be in state 1 (the out-of-control state), the right decision should be to stop the process, search for the assignable cause and remove it, thus causing the process to go back to its nominal condition. Otherwise, if the process is considered to be in state 0 (the in-control state), no stop should be performed and the process should continue.

Girshick and Rubin [1] derived the optimal rule required to detect the out-of-control state when the objective is to minimize the expected costs due to false alarms, restorations, and process operation.

2 Bayesian Control Charts

Clearly, the operating costs associated with the out-of-control state are assumed to be greater than the ones associated with the in-control state (otherwise there will be no economical reason to bring back the process to its nominal condition). As showed by Girshick and Rubin, the optimal control policy is Bayesian, since it is based the posterior probability that the process is out of control. In particular, let π_t represent the posterior probability that the process is out of control *after* the t th inspection epoch, that is after observing y_t . The optimal decision consists in issuing an alarm if:

$$\pi_t \geq \pi^* \quad (2)$$

where the threshold π^* depends on the costs associated to repair actions and operating conditions.^a If the alarm is issued, the process is inspected and, if the assignable cause is found, restored. After restoration, the process returns to the initial state (i.e., π_t is reset to π_0). If no alarm is issued, the process continues producing.

The posterior probability, which has a central role in the out-of-control condition (2), can be sequentially updated as summarized in Figure 1. In particular, the posterior probability that the process is out of control *after* observing y_t can be computed through Bayes' theorem:

$$\pi_t = \frac{\pi'_{t-1} f_1(y_t)}{\pi'_{t-1} f_1(y_t) + (1 - \pi'_{t-1}) f_0(y_t)} \quad (3)$$

where π'_{t-1} represents the prior probability that the process is out of control *before* observing y_t and can be computed as:

$$\pi'_{t-1} = \pi_{t-1} + (1 - \pi_{t-1})\gamma \quad (4)$$

where π_{t-1} represents the state of our knowledge after observing the previous $(t-1)$ th sample (see Figure 1) and $\gamma = 1 - e^{-\nu h}$ is the probability that the process shifted to the out-of-control state within the last h time units, given that it started in the in-control state.

Figure 1 Sequential update of the knowledge about the state of the process

Equations (3) and (4) can be used to sequentially update the process-state knowledge. Obviously, these equations require an initial value for the probability π_0 of starting at $t = 0$ in the out-of-control state. This initial value is usually set equal to zero to represent a perfect process setup.

By manipulating equation (3) slightly, we can obtain a different expression of the out-of-control rule, given by:

$$\ln \frac{f_1(y_t)}{f_0(y_t)} \geq \ln \left[\frac{(1 - \pi'_{t-1})}{\pi'_{t-1}} \frac{\pi^*}{(1 - \pi^*)} \right] \quad (5)$$

Therefore, the likelihood ratio $f_1(y_t)/f_0(y_t)$, which plays a relevant role in other control schemes such as the CUSUM control chart (*see Cumulative Sum (CUSUM) Chart*; [2]), has a central task in the Bayesian control charting, too. Furthermore, the Bayesian approach has another similarity with the CUSUM control chart. Both these monitoring schemes belong to the class of *memory control charts* [3]. Memory control charts, such as the moving-average (MA), the exponentially weighted moving-average (EWMA) (*see Exponentially Weighted Moving Average (EWMA) Control Chart*), and the CUSUM control charts, incorporate both present and past sample information in order to decide whether the process is deemed out of control. Despite this similarity, a key feature distinguishes the Bayesian approach from other memory control schemes. As noted by Basseville and Nikiforov [2], the Bayesian approach requires some knowledge of the process shift mechanism, which is not necessarily required in other memory control charts. In particular, it is based on the assumption of Poisson occurrence of the assignable cause and requires the availability of γ – the probability that the process shifts in the out-of-control state between two inspections epochs – in order to update the knowledge on the process state through equation (4).

In contrast with memory control charts, Shewhart approaches adopt a different scheme: at any given period the process is deemed out of control by considering only the last sample information. This is why Shewhart control charts can be referred to as *memoryless control charts*. Despite this main difference, a relationship between the Bayesian approach and the traditional Shewhart control charting can be outlined, as shown in [4]. This connection will be shown with reference to the $\bar{X}$ control chart (*see Control Charts for the Mean*). In this case, when the process

operates in the in-control state ($S_t = 0$), the quality characteristic X_t is normally distributed with mean equal to the target value μ_0 and variance σ^2 . On the other hand, when the process moves in the out-of-control state ($S_t = 1$), the quality characteristic X_t experiences a sudden shift in the mean level, which moves from μ_0 to $\mu_1 = \mu_0 + \delta\sigma/\sqrt{n}$. The assignable cause does not induce any change in the variance, which remains at the in-control level σ^2 . Each h time units, a sample of fixed size $n \geq 1$ is inspected to compute the sample mean $\bar{X}_t = \sum_{i=1}^n x_{ti}$. This sample mean is the observable quantity Y_t and has a **normal distribution** given by $f_j(y_t) = N(y_t; \mu_j, \sigma^2/n)$, where $j = \{0, 1\}$ represents the state S_t of the core process at time t . Given $f_0(y_t)$ and $f_1(y_t)$, the out-of-control condition (5) can be rewritten as:

$$-\frac{1}{(2\sigma^2/n)} \left[\left(y_t - \mu_0 - \frac{\delta\sigma}{\sqrt{n}} \right)^2 - (y_t - \mu_0)^2 \right] \geq \ln \left[\frac{(1 - \pi'_{t-1})\pi^*}{(1 - \pi^*)\pi'_{t-1}} \right] \quad (6)$$

which, after some easy manipulation, results in:

$$y_t \geq UCL_t = \mu_0 + \frac{k_t\sigma}{\sqrt{n}} \quad (7)$$

where

$$k_t = \delta/2 + 1/\delta \ln \left[\frac{(1 - \pi'_{t-1})\pi^*}{(1 - \pi^*)\pi'_{t-1}} \right] \quad (8)$$

The Shewhart $\bar{X}$ control chart has a quite similar scheme. The only difference is that the upper control limit UCL_t , which is designed to detect an increase in the mean, has a constant $k_t = k$ in equation (7). Therefore, the Bayesian approach can be interpreted as an adaptive Shewhart chart, where the position of the control limit adapts on line according to the information coming out from the process.

Figure 2 shows an example of this adaptive behavior for the simple case of $n = 1$. In this example, the in-control state is characterized by a target mean $\mu_0 = 5$, while the assignable cause induces a shift in the mean level at $\mu_1 = 6$. The assignable cause is supposed to arise at time $t = 21$. In spite of the process state, the variance of the quality characteristic is constant and equal to $\sigma^2 = 1$. The control limit in Figure 2 is computed assuming $\delta = 1$ (i.e.,

the control chart is designed to detect a shift size equal to 1σ), $\gamma = 0.002$, $\pi^* = 0.4$ and assuming that the process is known to start in the in-control state ($\pi_0 = 0$). As shown in Figure 2, the Bayesian control chart adapts the control limit UCL_t depending on the information coming out from the process. In particular, after the assignable cause occurred at time $t = 21$, the upper control limit starts to come closer and closer to the observed quantity until an out-of-control signal is issued at time $t = 27$.

Up to this point, the optimal policy was obtained by minimizing the expected total cost of operation and restorations. Therefore the Bayesian control rule described above is optimal when inspection costs can be neglected. In the last part of their paper [1], Girshick and Rubin revised the optimal policy described above, by including inspection costs in the objective function. In this case, the optimal control scheme can suggest skipping some inspections in order to minimize the expected costs. The resulting control policy can hence be defined as an “adaptive sampling interval” policy. In particular, the optimal policy consists in computing the posterior probability π_t that the process is out of control at time t and

continue production and skip the next inspection
if $\pi_t < \pi_1^*$

continue production and perform the next inspection

if $\pi_1^* \leq \pi_t < \pi_2^*$ (9)

stop production and search for the assignable cause

if $\pi_2^* \leq \pi_t$

where π_1^* and π_2^* are thresholds which can be computed by minimizing the expected costs.

Figure 2 An example of a Bayesian control chart

Extension of Bayesian Control Charting Based on the Posterior Probability that the Process is Out of Control

Starting from the basic scheme proposed by Girshick and Rubin [1], different authors studied this type of Bayesian control charting. In particular, the computation of the optimal thresholds in both the simple (equation 2) and the adaptive (equation 9) policies attracted the main interest of researchers. Taylor [5, 6] focused on the first type of Bayesian procedure, the one which neglects the inspection costs and is based on a unique threshold π^* . The author proposed a simplified approach aimed at deriving this threshold as a function of costs and system parameters, when small shifts are of interest. The approach proposed is based on results reported by Shiryaev [7], who studied a similar decision problem in continuous time.

More recently, different approaches [4, 8–13] focused on proposing a dynamic programming formulation to design the optimal Bayesian policy for finite production runs. Finite production runs arise when parts are processed in lots whose sizes are small and known in advance. After one lot has been processed, a setup (or maintenance) operation is executed and the process is brought back to an initial state. All the approaches presented showed that the Bayesian policy induces significant savings over traditional control charts, even when the same economic objective function is used to design both the approaches (for the economic design of traditional control charts, *see Economic Design of Control Charts*). In particular, Calabrese [8] and Porteus and Angelus [14] dealt with Bayesian control charts for attributes (*see Control Charts for Attributes*), assuming the fraction of nonconforming items as the quality characteristic of interest. Calabrese [8] also showed that the control problem can be formulated as a partially observable Markov decision process [9].

In his long-lasting interest on Bayesian control charts, Tagaras [4, 10–13] focused on control charts for variables (in particular, control charts to detect a shift in the level of the process, that is, $\bar{X}$ control charts). In his first work [4], Tagaras proposed a dynamic programming formulation to derive the optimal control policy when **adaptive sampling** intervals are allowed. In [10], the author further relaxed the assumption of fixed **sample size** and proposed a Bayesian control chart which allows

both adaptive sampling intervals and adaptive sample sizes. In [12], the performances of all the different Bayesian adaptive schemes (with or without adaptive sampling intervals and adaptive sample sizes) were compared. The main conclusion of this study was that most of the economic advantages can be achieved by allowing an adaptive sampling interval, even with a fixed sample size. In a recent paper, Tagaras and Nenes [13] further extended the Bayesian approach to a two-sided shift (increase or decrease) of the mean level.

Bayesian Control Charting Based on the Posterior Distribution of Process Parameters

The Bayesian approaches discussed in the previous section share a common structure, in which the alarm is issued on the basis of the posterior probability that the process is out of control. A different point of view considered in the literature, assumes that the out-of-control rule can be based on the posterior distribution of the parameter of interest. This posterior distribution can be sequentially computed *via* Bayes' theorem, since the posterior probability computed after observing the previous sample can be used as the prior before observing the current one. Approaches proposed in this area present many differences concerning the process parameter of interest, the in-control process model and the specific details of the out-of-control rule. In the following, these approaches will be reviewed outlining these specific features.

Although starting from an **estimation** problem, Chernoff and Zacks [15] formulated a Bayesian scheme to detect shifts in the process mean of a normally distributed quality characteristic. Given some knowledge on the shift mechanism, the posterior distribution of the process level is computed to check whether a shift has already occurred in a set of available samples. Given this specific objective of the proposed procedure, this approach can be adopted in the design stage, usually known as phase I, of control charting.

Wasserman and Sudjianto [16] proposed a control chart for a second-order dynamic linear model whose mean is subject to trends or level changes and attention is devoted to short production runs (*see Control Charts for Short Production Runs*). The

proposed control chart consists in computing mean and variance of the posterior distribution of the process level and then drawing a confidence band as in traditional Shewhart control charts (i.e., posterior mean plus and minus k times the posterior standard deviation). An alarm is issued if the nominal or target process level falls outside the control band.

Tsiamirizis and Hawkins (see **Statistical Process Control, Bayesian**; [17, 18]) proposed a Bayesian scheme for a process whose mean drifts according to a random walk when the process is in control. When an assignable cause occurs, the mean is subject to a random shock. As in [16], the parameter of interest is the process mean and the objective of the control chart is to detect a shift in the process mean. The authors proposed two out-of-control rules. The first is based on computing the posterior probability that the posterior mean crossed a given threshold. An out-of-control signal is issued if this probability is greater than a given value, which can in turn be related to the costs of type I and type II errors using a 0–1 loss function. The second out-of-control rule proposed is based on the Bayes factor, which gives the ratio of the posterior to prior odds.

Alt [19] proposed a Bayesian control chart for monitoring the mean of a multinormal process (see **Multivariate Control Charts Overview**). Again, the parameter of interest is the process mean and the out-of-control rule is based on the posterior mean and **covariance** matrix of the process level. The performance of this Bayesian approach is compared with the ones attained by different multivariate (CUSUM and EWMA) control chart in terms of the average run lengths (see **Average Run Lengths and Operating Characteristic Curves**).

Shiau and Feltz [20] proposed different Bayesian control charts for univariate and multivariate quality characteristics which can be continuous or categorical. Also in these approaches the posterior distribution plays a central role although an empirical Bayes approach is adopted in its computation.

Eventually, Bayarri and Garcia-Donato [21], presented a Bayesian control chart for attributes (see **Control Charts for Attributes**) aimed at monitoring the number of nonconformities (defects) per inspection unit. In this approach, the out-of-control rule is slightly different from the previous ones, since it is based on the posterior predictive distribution of the characteristic of interest.

This brief review shows the lack of a common framework in this second stream of research on Bayesian control charting. Clearly, approaches proposed in this area cannot be directly compared since they start from different assumptions on the in-control process model (with or without dynamic) and on the quality characteristic of interest (variable *vs* attributes, univariate *vs* multivariate variables). However, further effort could be usefully devoted to compare the different out-of-control rules proposed in order to provide an unifying guide for practical applications.

End Note

^a Girshick and Rubin [1] derived the optimal policy with reference to a slightly different function of π_t . However, the function they used is a monotonic increasing function of π_t . This is why the optimal policy can be directly expressed in terms of π_t .

Degradation Processes

Introduction

Many failure mechanisms in engineering, medical, social, and economic settings can be traced to an underlying **degradation** process. Most items under study degrade physically over time and a measurable physical deterioration almost always precedes failure. Examples of items that degrade over time are devices subject to wear in reliability and the immune system of HIV infected individuals in biostatistics. In an engineering setting, degradation is the irreversible accumulation of damage throughout life that leads to failure (*cf.* [1]) and may involve corrosion, material fatigue, wearing out, and fracturing. In the biosciences, degradation may be characterized by markers of health status and quality of life data.

Traditionally, statistical reliability **estimation** is mostly based on failure-time data. In practical applications, collecting samples of lifetimes can be time consuming and costly because the systems and devices under study are often highly reliable and expensive. An increasing emphasis on product reliability and short product-development cycles in industry results in few or no failures during reliability tests. Accelerated **life tests** can be used but the acceleration methods may not properly imitate the actual failure process and, even with acceleration, only few failures may occur. In reliability analysis, biostatistics, and econometrics longitudinal data on degradation and covariates are frequently available additionally to time-to-event data. In many cases, collecting degradation data may be difficult and costly but degradation data can provide much more reliability information than traditional failure-time data. When additional longitudinal data are available, an alternative approach to classical reliability and survival analysis is the modeling of degradation and environmental factors and of their failure-generating mechanisms by stochastic processes. This stochastic-process-based approach shows great flexibility and can give rise to new or alternative time-to-failure distributions defined by the **degradation model**. It is particularly useful when the application of traditional reliability models based only on failure and survival data is limited due to rare failures of highly reliable items or due to items operating in dynamic environments.

Models for Degradation Data

In engineering applications, degradation data can be obtained by direct measurements of **physical degradation** such as crack growth and tire wear. If actual physical degradation cannot be observed directly, surrogates like a deteriorating product performance parameter (e.g., power output), usage or exposure measures, and accumulated maintenance costs are usually referred to as *degradation data*, as well. In the biosciences, degradation data can be measurements of a biomarker like CD4 cell counts or quality of life data. As degradation is a complex random mechanism it is best represented by a stochastic process $X = \{X(t) : t \geq 0\}$. In most applications, the monotonicity of degradation paths is a reasonable assumption because most real degradation processes are increasing. However, there are situations in which degradation need not be increasing. For instance, fatigue cracks sometimes show a tendency to heal and CD4 cell counts may fluctuate. A further cause for nonmonotone degradation paths is the fact that degradation is measured with error and the missing monotonicity is due to the error term whereas the actual degradation is monotone. Degradation processes are frequently described by general path models and by processes with stationary and independent increments. More sophisticated models for degradation processes are Markov diffusion processes (e.g., the Ornstein–Uhlenbeck process), **Markov processes**, and marked point processes (*cf.* [2, 3]).

General Path Models

In applied literature degradation processes are frequently described by a general path model $X(t) = g(t, A)$, that is, by a stochastic process that depends on a finite dimensional random variable $A = (A_1, \dots, A_r)$ via a deterministic function g . In [4, 5], and [6], a Paris growth curve path model was used for alloy fatigue crack size data. Moreover, general path degradation models with linear, convex, and concave functions g were applied to tire wear, electronic component degradation, silicon solar cell degradation, and disk storage media (*cf.* [4, 5, 7, 8]). Meeker and Escobar [5] consider general path degradation models in more detail (*see also Degradation and Failure*).

2 Degradation Processes

Lévy Process Models

A Lévy process is a stochastic process with stationary and independent increments (*see Lévy Processes*). The application of such processes as degradation models can be based on the fact that in systems subject to shocks, the order of damage causing shocks is often irrelevant. So, the increments of the accumulated damage process are stationary and exchangeable random variables which is somewhat weaker than stationary and independent increments. The most widely used Lévy processes for degradation modeling are *compound Poisson processes*, the *Wiener process with drift*, and the *gamma process*. When degradation evolves as an accumulation of shocks, each of them resulting in a random degradation increment, a compound **Poisson process** is an appropriate model. It is given by $X(t) = \sum_{i=1}^{N(t)} X_i$ where N is a Poisson counting process jumping at shock times and $\{X_1, X_2, \dots\}$ is a sequence of independent identically distributed (i.i.d.) random variables that represent the random increments of degradation caused by shocks and that are independent of N . The Wiener process with drift is a Gaussian process given by $X(t) = x_0 + \mu t + \sigma W(t)$ where W denotes a standard **Brownian motion**, x_0 is some initial degradation level, and μ and σ are drift and variance coefficients. The Wiener process is the only Lévy process with continuous sample paths, however, its paths are not monotone. The gamma process has increasing sample paths but it is a pure jump process.

A Lévy process Y has linear mean and variance functions. To cover nonlinear degradation behavior a timescale $\tau = \tau(t)$ can be used, that is, a positive, increasing function of real time with $\tau(0) = 0$. The timescale drives the speed of deterioration and describes slowing or accelerating degradation in real time. It measures the physical progress of degradation and is referred to as operational time. For instance, Bagdonavičius and Nikulin [9] consider a linear timescale with an initial acceleration period

$$\tau(t) = \gamma_1 t + \gamma_2 (1 - \exp(-\gamma_3 t)), \quad \gamma_i > 0 \quad (1)$$

for tire protector wear and Whitmore and Schenkelberg [10]

$$\begin{aligned} \tau(t) &= 1 - \exp(-\gamma_1 t^{\gamma_2}) \text{ and} \\ \tau(t) &= t^{\gamma_1}, \quad \gamma_i > 0 \end{aligned} \quad (2)$$

in the context of self-regulating heating cables. The choice of τ depends on, whether degradation is unbounded or approaches a saturation point. A further possible form of the timescale is a **Box-Cox transformation**

$$\tau(t) = \begin{cases} \gamma_0((t+1)^{\gamma_1} - 1)/\gamma_1, & \gamma_1 > 0 \\ \gamma_0 \log(t+1), & \gamma_1 = 0 \end{cases} \quad (3)$$

To model the influence on failure of an item's dynamic operating environment, the timescale may depend on a covariate process Z , for instance on different loads, stress levels, or usage measures, that is, $\tau_Z(t) = \tau(t, Z)$. An example is the model of additive accumulation of damage:

$$\tau_Z(t) = \tau \left(\int_0^t \exp(\beta^T Z(s)) ds \right) \quad (4)$$

The degradation model is given by

$$X(t) = X_0 + Y(\tau_Z(t)) =: X_0 + Y^Z(t) \quad (5)$$

where Y^Z is the timescaled Lévy process Y and X_0 is some possibly random initial degradation level independent of (Y, Z) . Conditioned on $\{Z = z(\cdot)\}$, $Y^{z(\cdot)}$ is a process with independent but not stationary increments. Obviously,

$$\begin{aligned} E[X(t) | Z] &= E[X_0] + \mu \tau_Z(t) \quad \text{and} \\ \text{Var}[X(t) | Z] &= \text{Var}[X_0] + \sigma^2 \tau_Z(t) \end{aligned} \quad (6)$$

with $\mu = E[Y(1)]$ and $\sigma^2 = \text{Var}[Y(1)]$. For example, let the baseline degradation process Y be a Wiener process with drift $Y(t) = \mu t + \sigma W(t)$ so that the timescaled degradation process X is given by $X(t) = X_0 + \mu \tau_Z(t) + \sigma W(\tau_Z(t))$. This model is appropriate if the actual degradation process $\mu \tau_Z(t)$ is latent but observable with some additive error term which has a variance proportional to the actual degradation process.

Among others Wiener process degradation models have found application in [11] and [12]. Whitmore ([13]) applied a Wiener process model with error to degradation data of transistor gain. Wiener processes with a nonrandom timescale were used as degradation models for heating cables and carbon-film resistors in [10] and [14]. A bivariate Wiener process degradation model was considered in [15] and in [16] and applied to equipment degradation data in aluminum

production and to biomarker data of AIDS clinical trials. In these models, one process is a latent or unobservable degradation process and the second one represents a marker process that is correlated with the degradation process and tracks its progress. Degradation models based on the gamma process were considered in [17], [2], and with application to crack growth data in [18]. In [9] a gamma process with a random timescale was applied to tire wear, and in [19], both geometric Brownian motion and gamma processes were considered in a timescaled degradation model.

Models Relating Degradation and Failure

Considerable interest has focused on joint models for the distribution of the failure time T and the degradation process X . Two model classes, *threshold models* and *shock models*, predominate in the engineering context. In a threshold model, X is *failure defining* by $T = \inf\{t \geq 0 : X(t) \geq X^*\}$ where X^* is a critical threshold level which is possibly random. This kind of failure, where an item is regarded as failed and usually switched off when its degradation level first reaches a critical threshold, is called *soft failure* (cf. [5]) or *nontraumatic failure*. In a shock model the item or system is subject to external shocks which may be survived or which lead to failure. This kind of failure is referred to as *hard failure* (cf. [5]) or *traumatic failure*. The shocks usually occur according to a Poisson process whose intensity depends on degradation and environmental factors. In a shock model X is *failure rate determining*, which means, that the conditional failure rate of T

$$\lambda(t, X) = \lim_{\Delta \downarrow 0} \frac{1}{\Delta} P(t \leq T < t + \Delta \mid X, T \geq t) \quad (7)$$

determines the conditional survival function via the exponential formula

$$P(T > t \mid X) = \exp\left(-\int_0^t \lambda(s, X) ds\right) \quad (8)$$

The class of reliability models, which combines the ideas of hard and soft failures by considering them as **competing risks**, is called *degradation-threshold-shock models* (DTS models) (cf. [20]). In a DTS model, additionally to soft failures which are immediately related to degradation, an item may also

fail when a traumatic event like a shock of large magnitude occurs although the degradation process has not yet reached the threshold. So, the observable failure time of an item is the minimum of the moment when degradation first reaches a critical threshold and the moment when a censoring traumatic event occurs. General expressions of the failure-time distribution in a DTS model and of the likelihood function based on the observation of identically distributed degradation processes X_i of n independent items at discrete times, their failure times T_i , and their failure modes (hard or soft failure) were given in [20]. DTS models based on gamma and Wiener degradation processes were considered in [21] and [17]. **Maximum likelihood** and semiparametric estimation in a DTS model with a time scaled gamma degradation process was investigated in [9]. In the context of DTS models, Bagdonavičius *et al.* [22] consider a linear path model with time-dependent covariates and multiple traumatic event modes. Nonparametric estimators in general path DTS models with multiple traumatic failure modes and renewals were analyzed in [23]. A DTS model based on Lévy processes for repairable items was introduced in [24]. Singpurwalla [2] gave a detailed review on stochastic-process-based reliability models including DTS models and Tsatis and Davidian [25] gave an overview on joint modeling of longitudinal and failure data in biostatistics.

Hierarchical Markov Chain Monte Carlo (MCMC) for Bayesian System Reliability

Hierarchical Models

Hierarchical models are one of the central tools of Bayesian analysis. Broadly, Bayesian models have two parts (*see Bayesian Reliability Analysis*): the likelihood function and the prior distribution. We construct the likelihood function from the sampling distribution of the data, which describes the probability of observing the data before the experiment is performed. After we perform the experiment and observe the data, we can consider the sampling distribution as a function of the unknown parameters. This function is called the likelihood function. The prior distribution describes the uncertainty about the parameters of the likelihood function. We update the **prior distribution** to the posterior distribution after observing data. We use Bayes' theorem to perform the update, which shows that the posterior distribution is computed (up to a proportionality constant) by multiplying the likelihood function by the prior distribution.

Denote the sampling distribution as $f(\mathbf{y} | \theta)$ and the prior distribution as $g(\theta | \alpha)$, where α represents the parameters of the prior distribution (often called *hyperparameters*). It may be the case that we know $g(\theta | \alpha)$ completely, including a specific value for α . However, suppose that we do not know α , and that we choose to quantify our uncertainty about α using a distribution $h(\alpha)$ (often called the *hyperprior*). This is the most general form of a hierarchical model. A hierarchical model has three parts [1]:

1. The *observational model* for the data.

$$(Y_i | \theta) \sim f(y_i | \theta), \quad i = 1, \dots, k \quad (1)$$

2. The *structural model* for the parameters of the likelihood.

$$(\theta | \alpha) \sim g(\theta | \alpha) \quad (2)$$

3. The *hyperparameter model* for the parameters of the structural model.

$$\alpha \sim h(\alpha) \quad (3)$$

While this is the most general form of the hierarchical model, one of its most common applications is in problems where there are multiple parameters that are related by the structure of the problem. Consider the data in Table 1, which are analyzed in [2] and [3]. These data summarize the number of failures of pumps (s_i) over a period of time (t_i) in several systems (i) of the nuclear power plant Farley 1.

What is the appropriate observational model for the data in Table 1? We could assume that each pump has an identical failure rate, λ . We could then model the number of failures as $S_i \sim \text{Poisson}(\lambda t_i)$, $i = 1, \dots, 10$, or equivalently, $\sum_{i=1}^{10} S_i \sim \text{Poisson}(\lambda \sum_{i=1}^{10} t_i)$.

The assumption of a common failure rate, however, is quite strong and may be inappropriate. Suppose that instead of a common failure rate, we consider the failure rate for each pump, λ_i , as a sample from an overall population distribution. We have no information, other than the data, that distinguishes the failure rates, and we have no ordering or grouping of the rates. Formally, this suggests that we treat the rates as *exchangeable*, which implies that their joint distribution $g(\lambda_1, \dots, \lambda_{10})$ is invariant to permutations of the indices of the parameters.

By treating the rates as exchangeable, we propose the following hierarchical model:

1. An *observational model* for the data.

$$(S_i | \lambda_i) \sim \text{Poisson}(\lambda_i t_i), \quad i = 1, \dots, 10 \quad (4)$$

Table 1 Pump failures (t_i in thousands of hours)

System _{i}	s_i	t_i
1	5	94.320
2	1	15.720
3	5	62.880
4	14	125.760
5	3	5.240
6	19	31.440
7	1	1.048
8	1	1.048
9	4	2.096
10	22	10.480

2 Hierarchical MCMC for Bayesian System Reliability

2. A *structural model* for the parameters of the likelihood.

$$(\lambda_i | \alpha, \beta) \sim \text{Gamma}(\alpha, \beta), \quad i = 1, \dots, 10 \quad (5)$$

3. A *hyperparameter model* for the parameters of the structural model.

$$\alpha \sim \text{Uniform}(0.0, 5.0) \quad (6)$$

$$\beta \sim \text{Gamma}(0.1, 1.0) \quad (7)$$

This model allows the pump for each system to have its own failure rate, but it also models each failure rate as coming from a common population distribution. This hierarchical structure allows us to *borrow strength* for the **estimation** of each λ_i . In particular, the estimation of each λ_i is improved by using the failure data from the other pumps.

Markov Chain Monte Carlo (MCMC)

Given the hierarchical model for the data in Table 1, we now need to estimate the posterior distributions for λ_i , $i = 1, \dots, 10$, α , and β . The posterior distribution is proportional to

$$\begin{aligned} & p(\lambda_1, \dots, \lambda_{10}, \alpha, \beta | \mathbf{s}, \mathbf{t}) \\ & \propto \exp\left(-\beta - \sum_{i=1}^{10} (\beta + t_i) \lambda_i\right) \left(\prod_{i=1}^{10} \lambda_i^{s_i + \alpha - 1}\right) \\ & \quad \times \beta^{10\alpha + 0.1 - 1} (\Gamma(\alpha))^{-10} I(\alpha \in (0, 5)) \end{aligned} \quad (8)$$

(For more details on the derivation, see [3].)

In Bayesian analysis, the posterior distribution provides the “answer”; however, it is not immediately obvious how to use this expression for $p(\lambda_1, \dots, \lambda_{10}, \alpha, \beta | \mathbf{s}, \mathbf{t})$ to answer questions of interest. In particular, suppose that we would like to know the expected rate of failure for an arbitrary pump from this population, given the observed data. Mathematically, we need to calculate

$$\int \frac{\alpha}{\beta} p(\lambda_1, \dots, \lambda_{10}, \alpha, \beta | \mathbf{s}, \mathbf{t}) d\lambda_1, \dots, d\lambda_{10} d\alpha d\beta \quad (9)$$

Monte Carlo integration can approximate this integral: we draw a sample $X^{(j)} = (\lambda_1^{(j)}, \dots, \lambda_{10}^{(j)}, \alpha^{(j)},$

$\beta^{(j)})$, $j = 1, \dots, n$, from $p(\lambda_1, \dots, \lambda_{10}, \alpha, \beta | \mathbf{s}, \mathbf{t})$ and then calculate $\sum_{j=1}^n \alpha^{(j)} / \beta^{(j)}$. **MCMC** provides the algorithms to generate the random sample from the posterior distribution – or more generally, from any distribution, $\pi(\cdot)$, of interest. The strategy is to construct a Markov chain with $\pi(\cdot)$ as its stationary distribution.

A Markov chain is a sequence of random variables $\mathbf{X}^{(j)}$, $j = 0, \dots$, so that for each j , $\mathbf{X}^{(j)}$ is sampled from a distribution $P(\mathbf{X}^{(j)} | \mathbf{X}^{(j-1)})$. Given $\mathbf{X}^{(j-1)}$, the next state $\mathbf{X}^{(j)}$ depends only on $\mathbf{X}^{(j-1)}$ and not on the rest of the history of the chain. The sequence is called a *Markov chain*, and $P(\cdot | \cdot)$ is called the *transition kernel* of the chain. Subject to certain regularity conditions [4], the chain, regardless of its starting value $\mathbf{X}^{(0)}$, eventually converges (after a *burn-in* of m samples) to a unique stationary distribution. As j increases, the samples $\mathbf{X}^{(j)}$ become dependent samples approximately from $\pi(\cdot)$.

Constructing a Markov chain with the appropriate stationary distribution is straightforward using the *Metropolis-Hastings algorithm* [5]. Suppose that we want to draw $\mathbf{X}^{(j+1)}$. We sample a *candidate* point $\mathbf{Y}$ from a *proposal distribution* $q(\cdot | \mathbf{X}^{(j)})$. The proposal distribution may depend on the current point $\mathbf{X}^{(j)}$. The candidate point is accepted (i.e., $\mathbf{X}^{(j+1)} = \mathbf{Y}$) with probability $\alpha(\mathbf{X}^{(j)}, \mathbf{Y})$, where

$$\alpha(\mathbf{X}, \mathbf{Y}) = \min\left(1, \frac{\pi(\mathbf{Y})q(\mathbf{X} | \mathbf{Y})}{\pi(\mathbf{X})q(\mathbf{Y} | \mathbf{X})}\right) \quad (10)$$

Otherwise, $\mathbf{X}^{(j+1)} = \mathbf{X}^{(j)}$. The rate of convergence depends strongly on the relationship of the stationary distribution and the proposal distribution. See [4] for strategies on choosing good proposal distributions.

There are canonical choices for proposal distributions. The *Metropolis algorithm* uses symmetric proposals, where $q(\mathbf{Y} | \mathbf{X}) = q(\mathbf{X} | \mathbf{Y})$. A special case of the Metropolis algorithm is *random-walk Metropolis*, where $q(\mathbf{Y} | \mathbf{X}) = q(|\mathbf{X} - \mathbf{Y}|)$. The *independence sampler* [6] has a proposal density that does not depend on the current state of the chain, $q(\mathbf{Y} | \mathbf{X}) = q(\mathbf{Y})$. Independence samplers work well when $q(\cdot)$ is a good approximation to $\pi(\cdot)$ but with heavier tails.

Two of the most widely used choices for proposal distributions are the *single-component Metropolis-Hastings algorithm* and the *Gibbs sampler*. Instead of updating the entire vector $\mathbf{X}$ in one step, these algorithms update smaller groups of the components of $\mathbf{X}$ – often only one component at a time. Let $\mathbf{X} =$

$(X_1, \dots, X_p)$ and let $\mathbf{X}_{-i} = (X_1, \dots, X_{i-1}, X_{i+1}, \dots, X_p)$. Define the *full conditional distribution* of X_i as the distribution of the i th component of $\mathbf{X}$ conditional on all of the remaining components, $\mathbf{X}_{-i}$. If $\mathbf{X} \sim \pi(\cdot)$, the full conditional distribution of X_i is

$$\pi(X_i | \mathbf{X}_{-i}) = \frac{\pi(\mathbf{X})}{\int \pi(\mathbf{X}) dX_i} \quad (11)$$

The single-component Metropolis-Hastings algorithm generates candidate points Y_i from proposal densities $q_i(Y_i, X_i^{(j)}, \mathbf{X}_{-i}^{(j)})$, where $\mathbf{X}_{-i}^{(j)} = (X_1^{(j)}, \dots, X_{i-1}^{(j)}, X_{i+1}^{(j-1)}, \dots, X_p^{(j-1)})$, so that components with indices smaller than i have already been updated j times. The acceptance probability for Y_i is

$$\alpha(X_{-i}, X_i, Y_i) = \min \left(1, \frac{\pi(Y_i | \mathbf{X}_{-i}) q_i(X_i | Y_i, \mathbf{X}_{-i})}{\pi(X_i | \mathbf{X}_{-i}) q_i(Y_i | X_i, \mathbf{X}_{-i})} \right) \quad (12)$$

The Gibbs sampler [7] is a special case of the single-component Metropolis-Hastings algorithm where the proposal distribution is the full conditional distribution,

$$q_i(Y_i, X_i^{(j)}, \mathbf{X}_{-i}^{(j)}) = \pi(Y_i | \mathbf{X}_{-i}) \quad (13)$$

The acceptance probabilities for the Gibbs sampler are all one.

Application to Bayesian System Reliability

For illustration, suppose that we have a simple parallel system (*see Parallel, Series, and Series-Parallel Systems*) that comprises the 10 pumps described in Table 1. The system works if at least one of the pumps is working. We would like to estimate the probability that the system is working at 10 000 h. (Remember that the times in Table 1 are in thousands of hours.) Because we describe the number

of failures as a Poisson process (*see Poisson Processes*), $\text{Poisson}(\lambda_i t_i)$, the time to the first failure of a pump is distributed $\text{Exponential}(\lambda_i)$. Assume for this example that once a pump fails, it is not repaired. (Of course, in a real nuclear power plant, pumps are always repaired.) We would like to estimate the probability, $R_S(t)$, that the system is working at 10 000 h. The probability that the system is working at 10 000 h is $R_S(10) = 1 - \prod_{i=1}^{10} (1 - \exp(-10\lambda_i))$. (See [8] for the derivation of the expression for system reliability.)

We use a combination of the Gibbs sampler and single-component Metropolis-Hastings algorithm to estimate the failure rates for each pump. This requires the full conditional distributions for each parameter.

$$[\lambda_i | \lambda_{-i}, \alpha, \beta] \sim \text{Gamma}(s_i + \alpha, \beta + t_i) \quad (14)$$

$$[\beta | \alpha, \lambda_1, \dots, \lambda_{10}] \sim \text{Gamma} \left(10\alpha + 0.1, 1.0 + \sum_{i=1}^{10} \lambda_i \right) \quad (15)$$

$$[\alpha | \beta, \lambda_1, \dots, \lambda_{10}] \propto \left(\prod_{i=1}^{10} \lambda_i^{s_i + \alpha - 1} \right) \beta^{10\alpha - 0.9} (\Gamma(\alpha))^{-10} \times I(\alpha \in (0, 5)) \quad (16)$$

For the $(j+1)$ st iteration of MCMC, for $i = 1, \dots, 10$, we set $\lambda_i^{(j+1)}$ equal to a random draw from a $\text{Gamma}(s_i + \alpha^{(j)}, \beta^{(j)} + t_i)$ distribution, and we set $\beta^{(j+1)}$ equal to a random draw from a $\text{Gamma}(10\alpha^{(j)} + 0.1, 1.0 + \sum_{i=1}^{10} \lambda_i^{(j+1)})$. To sample $\alpha^{(j+1)}$, we set a candidate point Y equal to a random draw from a proposal distribution: for example, $\text{Normal}(\alpha^{(j)}, 0.25)I(0 < \alpha < 5)$. As a general heuristic, we choose the standard deviation of the proposal distribution so that the candidate acceptance probability is between 0.25 and 0.45 [9]. For this proposal distribution, the candidate acceptance probability is

$$\min \left(1, \frac{\prod_{i=1}^{10} (\lambda_i^{(j+1)})^{s_i + Y - 1} (\beta^{(j+1)})^{10Y - 0.9} \Gamma(Y)^{-10}}{\prod_{i=1}^{10} (\lambda_i^{(j+1)})^{s_i + \alpha^{(j)} - 1} (\beta^{(j+1)})^{10\alpha^{(j)} - 0.9} \Gamma(\alpha^{(j)})^{-10}} \right) \quad (17)$$

Figure 1 The posterior distribution of $R_S(10)$, the system reliability at 10 000 h

We could also use a MCMC package like WinBUGS [10] to perform the calculations.

Once we have a sample from the posterior distribution, we evaluate $R_S(10)$ for each draw. The posterior mean of $R_S(10)$ is 0.92, with a 95% credible interval of (0.77, 0.99). Figure 1 is a plot of the posterior distribution of the system reliability at 10 000 h. (For more information on creating summaries using MCMC draws, see [11].)

Summary

Hierarchical models offer many advantages including the ability to borrow strength, to estimate individual parameters and the ability to specify complex models that reflect engineering and physical realities. MCMC provides a general set of algorithms that enable Bayesian inference in a variety of complex models.

Life Cycle Costs and Reliability Engineering

Introduction

Life cycle cost (LCC) is the total cost of a system or product over its entire life span. It includes the cost of design, production, operation, maintenance, warranty, and decommission or disposal. This cost is extremely critical as it is one of the most critical factors in decision-making regarding the procurement of a product or system. It is usually calculated using a simple payback measure such as the present or future value of the cost or using complicated analysis such as the analytical hierarchy process and others for comparing alternatives, especially when some of the cost components are intangibles.

LCC analysis became common in 1960s when government agencies and others used it as a criterion in procurement decisions. Since then it has been widely used in industry, business, and government agencies in many applications ranging from simple office equipment to complex engineering structures such as large-scale communications networks. Most of the cost components are common for these applications while others are not. For example, nonrepairable products such as satellites may not include the cost of repair and perhaps the cost of disposal. The first of these costs is a reliability-related cost. Owing to the fact that LCC can indeed encompass many cost components and it is difficult, if not impossible, to discuss all of them, this chapter focuses on LCC elements related to reliability engineering. The use of LCC analysis in reliability engineering is widely used in the automotive industry, which prompted the Society of Automotive Engineering (SAE) to advocate the reduction of LCC for equipment in the automotive sector by demonstrating why reliability and maintainability must be included in up-front decisions for strategic and tactical issues of achieving the lowest long-term cost on ownership as discussed in [1, 2]. In the following sections we intend to address the issues related to the LCC when considering reliability engineering in product or system design and procurement.

Products and systems consist of components arranged or configured in a specific arrangement that produces the desired functions. Therefore, the reliability of the components has a profound effect on
